### THE MASSACHUSETTS LUNACY LAW.

*Read in the Section of Medical Jurisprudence, at the Fortieth Annual Meeting of the American Medical Association, June 1886.*

BY T. W. FISHER, M.D.,  
OF BOSTON, MASS.

The question of a revision of the lunacy laws of Massachusetts has excited much interest the past year, and may soon become the subject of legislative inquiry. Dr. Stephen Smith, ex-Lunacy Commissioner of New York, has published a "Report on the Commitment and Detention of the Insane," which recommends uniform legislation on these subjects.

Patients are now admitted at the Boston Lunatic Hospital in six different ways. The majority of them are regularly committed by the Judge of Probate on the certificate of two physicians. There is little to criticise in the law by which this is done, except the provision which forbids physicians connected with asylums from certifying. This is a reflection on their honesty not warranted by any experience in this country. The large number of private Asylums in England, kept by medical men for profit, rendered desirable a law that no physician should certify a patient into his own asylum. This law was transplanted to this country—where private asylums are rare—and changed so as to forbid any physician connected in any way as officer, or trustee, or commissioner, or member of a board of lunacy even, with any hospital for the insane, public or private, from certifying a private patient into any hospital for the insane. This is not only a gratuitous insult to the specialty, but a hardship to the friends of the insane. Superintendents of hospitals—especially in country districts—are the only physicians whose knowledge of insanity is of much value. Such an one's advice is naturally sought by the relative of the patient in obscure cases, and it is something of a shock to be told, after receiving his valuable opinion and advice, that his certificate is of no value. His opinion in court may settle questions of damages of large amount, or determine the disposition of large fortunes by will; the life or death of an insane criminal may

depend on his judgment; but having advised so simple a thing as hospital treatment for some private patient, two strange physicians must be called in, at added cost, to reexamine the person, before he can be sent to a hospital for treatment. Fortunately, the provision of law, that the judge may see the insane patient, is not mandatory. If it was, it would be impossible, or at least harmful, to many patients to carry it into effect in Suffolk county. Here 500 or 600 patients are committed annually by one judge, and he is necessarily obliged to give some formal reason for not seeing the patient. This provision is merely superfluous, as a judge could insist on seeing a patient without it.

The second form of admission is upon emergency papers. This method, though of general application, is in use only in Suffolk county, and at this hospital, no emergency cases being reported by the State hospitals. The emergency law was passed to allow excited and dangerous patients to be speedily admitted to hospitals for temporary detention, and to prevent the necessity of insane persons arrested by the police of Boston, on Sundays, holidays, and after business hours, when no judge can be found, being sent to the station-houses or city prison. This was an excellent object, and the law is absolutely necessary for the safety of the public and the good of the insane. Instead, however, of being simple and easy of application, more papers are required, more time is necessary, and the method is more complicated than that for a regular commitment. In an emergency, having an excited lunatic to dispose of, few physicians remember the law, or know where to look for it, and either make out faulty certificates, which cannot be received, or send the patient with his friends or by the police to the hospital without any papers. In a regular commitment, which many physicians have learned to understand, the two physicians sign the same certificate; while the emergency law requires them to sign separate ones, and also to add to the usual form the statement that the patient is sent as an emergency case, *i. e.*, that he is so insane that he cannot wait for the regular commitment process. We very seldom receive correct emergency certificates, except from the examining physicians to the Board of Directors.

This necessitates, when such a case arrives, the rejection of the faulty papers, and sending out into the city for two other physicians living nearest the hospital, who are strangers to the patient but able to certify properly. This puts the relatives to the expense of four physicians instead of two, and causes the prolonged detention of an excited patient in an out reception-room. Humanity requires that these cases should be received, but we cannot admit them to the wards without the proper certificates. Another absurdity of this law is the requiring of a bond of \$100.00 to be given by somebody representing the patient, to remove him within five days unless regularly committed. No superintendent would dare to keep the patient beyond the legal limit; as he would expose himself at once to a suit for illegal detention and heavy damages. In the great majority of cases, however, the bond is a mere form which might be dispensed with. It is either signed by some poor and irresponsible friend of the patient, or by some policeman, or, more often still, by one of the certifying physicians. Another absurd provision is that requiring that the mayor or one of the selectmen should sign the application. In Boston, where most of these cases occur, the law is evaded in the following manner (if it were literally enforced very few emergency cases would be received. It would be as easy to find the judge as to find the mayor or his representative): The Mayor of Boston delegates his authority both under the emergency law and the law for regular commitment, to the Board of Directors for Public Institutions. In the latter case the clerk of the Board signs for the Mayor an acknowledgement that he has been notified and puts it on file. In the former case he signs in advance blank applications for the admission of emergency cases, and gives them in charge to the Superintendent of this hospital and the examining physicians of the Board. Suppose the police or the relatives of an excited lunatic had to find this official at short notice, by night, or on a holiday, or on Sunday, as usually occurs, how often would the delay prove dangerous? These deviations from a strict interpretation of the laws relating to the commitment of the insane are at present humane and necessary, and I fully approve them. I think, however, that the red tape and complicated requirements of the emergency law stand in the way of its general usefulness, especially in the small cities and towns. Before the physicians of a country village could have found and read the law and made proper certificates, and invented a form of bond, and found a selectman who knew how to make an application, the lunatic might have murdered his family or burned the town. Practically, the law is not used in the country or outside of Boston. The violent lunatic is seized by the local police or town constable, handcuffed, and put

into the lock-up to await the slow action of the regular process of commitment before a judge of probate in some distant town, perhaps. The whole procedure in emergency cases should be simplified so as to consist merely in the sworn certificate of two physicians as to the dangerous condition of the lunatic.

The admission of voluntary patients is the third method to be considered. A recent law allows the Superintendent to receive as a "boarder" any person who makes written application to that effect "whose mental condition is not such as to render it legal to grant a certificate of insanity." This law, strictly construed, would prevent the admission of any insane person, or dipsomaniac, as a voluntary patient. This would only leave a certain class of nervous patients, who were apprehensive of becoming insane, and were desirous of early treatment as a means of prevention, to be admitted under this law. Applications of this kind are very rare at the public hospitals. The McLean Asylum, at Somerville, has almost a monopoly of this class of patients, and I am afraid many of the cases admitted there and elsewhere do not come within the terms of the law. A few inebriates have been admitted to the Boston Lunatic Hospital as voluntary patients, by order of the Board and otherwise, and some of them have remained a long time under treatment, and have apparently recovered.

Some patients, no doubt, are made willing to come voluntarily by the threat of commitment held over them by their relatives, and the knowledge that they can go on three days' notice by another written application for discharge. It is certain that some insane persons are admitted as voluntary patients; also, that many become insane and are committed before the three days' grace are over. It seems a breach of confidence on the part of the superintendent to have a voluntary patient committed, and yet it often becomes necessary. The opinion of Dr. Cowles, of the McLean Asylum, would be of especial value with reference to this law. It seems to me, however, that I should change it, so as to allow any person—sane or insane, or a dipsomaniac—admission on his voluntary application; but with the definite understanding that he was liable to be committed if his case proved serious or intractable. The term "boarder" is somewhat obscure. Does it mean a private patient, or simply an inmate, without regard to the payment of board? If the latter, may not a desire to be comfortably cared for at public expense induce some to apply? The law depends largely on the discretion of the superintendent for its successful application.

The fourth form of admission is under the Habitual Drunkard law.<sup>1</sup>

<sup>1</sup> Since this paper was read a law has been passed providing a special hospital for inebriates.

This law, as it stands, is defective, and liable to abuse in several ways. In the first place, inebriates should be committed to some special institution, and not to lunatic hospitals. They not only take up the room needed by the insane, but, after the first few days, they are practically sane, and find themselves surrounded by the depressing influences of an insane hospital, and subjected to restraints and regulations primarily adapted to the insane. To be sure they are better off than when at large, exposed to temptations to drink, and much may be done for them in the way of kind treatment and moral management. But they are out of place, and they often feel it, and show it; while many are considerate and give little trouble, sometimes they interfere sadly with the discipline and interrupt the harmony of an asylum ward. They may refuse to associate with the insane or claim privileges which cannot be granted their insane neighbors and which, if granted them, cause more or less jealousy and hard feeling.

In the second place, they should be committed for a definite time, either for one, two or three years. This is necessary, because a long course of hygienic treatment is required to restore the enfeebled brain to its normal state of health and vigor, and to allow the weakened will to regain ascendancy over the appetite for stimulants. The inebriate's whole constitution needs reconstructing, and this process must not be interrupted by occasional drinking. It is better, also, for the inebriate to know definitely what he is to look forward to, so as to ensure contentment and repose of mind as far as possible. The patient should expend his energies in healthful employment, and in the attempt at recovery, and not in efforts for his own release. The present law subjects the superintendent to constant importunities for discharge on the part of the inebriate and his friends. Plausible reasons are advanced, ingenious schemes are made use of, and all sorts of influence brought to bear for a patient's discharge, when one would have supposed that removal from home for a year would have been a great relief to the inebriate's family and friends.

I have endeavored to conform to the rule here that no habitual drunkard shall be discharged under a year's detention, as that was the shortest period of commitment ever proposed in the discussions in Legislature and Parliament. I failed in applying this rule in almost the first case committed. After a two months' residence, this person was allowed to go home on trial, at the personal request of the judge who committed him, to avoid a long and unprofitable rehearing of the whole case on its merits. Fortunately, this patient has so far justified the confidence reposed in him, and has been discharged.

In the third place, the law should allow compulsory labor to be performed by inebriates, with-

in certain limits, and at the discretion of the superintendent, partly to reimburse the Commonwealth for their support, but more especially as a hygienic measure. Idleness in the wards of a lunatic hospital is as far as possible from the best treatment of inebriety. Varied employment, in the open air when possible, for a few hours daily, with similar periods for recreation out of doors, is the essential feature of such treatment. The majority of insane persons are unable to work, while most inebriates are. It would be wrong to compel an insane person to work, while inebriates might be induced to work, by promise of reward, deprivation of privileges, and other forms of moral suasion. The opportunities for work in most hospitals are already too limited, and lack in variety, while in an inebriate asylum there would be no objection to the use of tools of any kind.

The law is also liable to abuse in several ways. In the first place, physicians are not unlikely to apply the law to some inebriates who are not of unsound mind. The use of both terms, "dipsomaniac" and "habitual drunkard," tends to create confusion and ambiguity in certifying. Dipsomania, either inherited or acquired, would be a proper cause of commitment. Persons affected with an inherited tendency to that form of impulsive insanity, characterized by an insane desire to drink, are dipsomaniacs by inheritance. These cases are rare; they have a defective or degenerated cerebral organization which leads them to impulsive acts through a weakness of the will, and excessive energy of the animal instincts. In another more numerous class the brain has been so damaged by inebriety or other causes, such as ill health, blows on the head, sun-stroke, etc., as to prevent all possibility of self-control in relation to drink. These are cases of acquired dipsomania. Persons of sound mind who drink habitually from choice are not proper subjects for commitment. They are vicious drunkards, and should be punished rather than treated. These are nice distinctions it is true; but they are real ones, and it is therefore important that physicians should look carefully for the element of unsoundness of mind in the cases they are called on to examine.

There is also some danger that judges may not sufficiently regard the clause which requires that satisfactory evidence shall be furnished that the inebriate is not a person of bad repute or of bad character apart from his habits of inebriety. Such evidence is not likely to be presented unless demanded and the facts carefully elicited from reluctant witnesses. It would, indeed, be unfortunate if our insane hospitals should be used as convenient retreats for vicious and disreputable drunkards to recuperate in.

For many years there have been attempts on the part of superintendents of insane hospitals to secure the passage of a law allowing the commit-

ment of dipsomaniacs to some special institution for their custody and treatment. In England this movement resulted, after many years of discussion in Parliament, in the passage of an Habitual Drunkard's Bill, whereby such persons may voluntarily seclude themselves in special institutions for definite periods. The writer has often advocated before legislative committees and the Board of Health, Lunacy and Charity, and in a paper on "Insane Drunkards" read before the Massachusetts Medical Society in 1879, legalizing the commitment of inebriates to special institutions for long periods of from one to three years. He also demonstrated, in defending an action for damages for improper certification of an inebriate, at considerable trouble and expense, that, in the opinion of the Supreme Court of Massachusetts, there is such a disease as dipsomania, and that, in the absence of special institutions, such cases might be committed to hospitals for the insane. Soon after this decision, if not in consequence of it, renewed efforts were made by the Board of Health, Lunacy and Charity to secure the passage of a law on this subject, and in 1885 the following law, not wholly in accord with their recommendation, was passed:

*An Act Concerning Hospital Treatment for Certain Persons Subject to Dipsomania or Habitual Drunkenness.*

*Be it enacted, etc., as follows:*

SECTION 1. Whoever is given to or subject to dipsomania, or habitual drunkenness, whether in public or in private, may be committed to one of the State lunatic hospitals; *provided, however,* that no such person shall be so committed until satisfactory evidence is furnished to the judge before whom the proceedings for commitment are had that such person is not of bad repute or of bad character, apart from his habits of inebriety.

SECT. 2. The provisions of chapter eighty-seven of the Public Statute, and of acts amendatory to such chapter, relative to the commitment of an insane person to a lunatic hospital, shall be applicable to, and shall govern the commitment of, any person under this act except that in all proceedings relative to the commitment of any such person it shall be specifically alleged that he is subject to dipsomania, instead of alleging that he is insane.

SECT. 3. All the laws relative to persons committed to lunatic hospitals on the ground of insanity shall apply to persons committed thereto under the provisions of this act; *provided,* that no person so committed shall be discharged therefrom unless it appears probable that he will not continue to be subject to dipsomania or habitual drunkenness, or that his confinement therein is not longer necessary for the safety of the public or for his own welfare.

SECT. 4. This act shall take effect upon its passage.  
*Approved June 18, 1885.*

It will be seen this act does not include this hospital in its provisions; but it has been construed as applying to it by the committing magistrate. The provision allowing commitment to lunatic hospitals may have been a compromise on the part of the legislature to avoid the expense of establishing a special institution for inebriates. It certainly was not what superintendents had

asked for, but what they had always earnestly protested against. They had hoped for a law to relieve them of such inebriates as did from time to time get committed to their hospitals on the claim that they were insane; and a law was passed legalizing the commitment to insane hospitals of habitual drunkards without any inquiry as to their sanity. This law was passed in the face of the fact that all the hospitals were full to overflowing with cases of ordinary insanity, so that hundreds were compelled to sleep in the attics and on corridor floors. Under this pressure one superintendent expressed himself as having degenerated into a big policeman, spending his time in trying to keep order and maintain discipline in a crowd of lunatics and inebriates, instead of devoting his time to his proper work of treating insanity.

The fifth method is by transfer from State hospitals for the insane. This has never been made use of in the history of the hospital until the past year. In fact, it was by Chapter 319 of the Acts of 1886 that it was first authorized. This provides that the order of commitment of an insane person, whose friends are unable to support him, holds good until his recovery, and he may be transferred, by the State or city authorities, to any "hospital, asylum, private dwelling, or other place," at their discretion, provided he has had a trial of hospital treatment, and has been insane twelve months. After this initiation, he may be subject for a lifetime, if he does not recover, to the control of the State, civic, or town authorities. He may be transferred from one asylum to another, regardless of the convenience or contiguity of his friends and relations. Boston patients, for instance may be, and are, sent to Northampton. He may be boarded out in some remote village, possibly to be overworked, underfed, and seldom visited by friends or inspectors. Ignorant and economical selectmen may without medical advice seclude him in some remote poor-house, or they may board him or farm him out on some distant farm. This control only ends with the life of the patient, and he may be still held by his first commitment paper years after the physicians who examined him and the judge who committed him are dead and forgotten. This is called "administrative commitment." If exercised by medical men, experienced in dealing with the insane, and humane men, remembering that the love of home and friends is not always extinguished in the insane at the end of twelve months, and that many recoveries occur after one year, and even after five years of insanity, it may not work much harm to the insane. If the selection of the boarded-out insane is very carefully made, and their inspection very thoroughly conducted by competent physicians, having experience in the treatment of insanity, not much harm may be done, and some money may be saved to the State.

I think, however, the law is rather in the interests of economy and administrative convenience than for the best good of the insane. An insane person's family and friends are the natural inspectors and supervisors of his treatment and condition. I see no reason why, because an insane person is poor and may never fully recover, he should be moved all over the State, like a pawn on a chessboard, because this or that hospital is too full, or because he can be boarded out at \$2 a week, while it costs \$4 at the State hospitals. Since writing the above I have read Dr. Park's last report, from which I extract the following: "Some forty chronic and incurable cases were transferred to the Tewksbury Almshouse and the Westboro' Hospital, and their places supplied by an equal number of similar cases from Danvers. Apart from the temporary pleasure of the day's outing, including the ride on the cars, which was afforded them by this trip, no improvement in their mental condition can be expected as a result of their change of residence."

The sixth method of admission is by the return of excited patients from the Retreat at Dorchester. We have received ten patients in this way—under a general order of the Board to take all patients sent to us by the superintendent of that institution. Nine of them were originally sent there under a similar order. The other case was that of a man who has lived in four different hospitals in the last two years on one commitment. I do not know whether the patients sent from this hospital to the Retreat were sent under the law of 1886 or not; if so, the original papers did not accompany them. There is a law which is open to criticism, but we have been exempted from its operation. It directs that all those insane committed from Suffolk County unable to pay board shall be sent in turn, and in equal numbers to each of the State hospitals and this hospital. At first commitments were made for six weeks to each of the above hospitals, including the Homeopathic Hospital, without regard to the question whether patients desired homeopathic treatment or not. This hospital was early exempted from the operation of this law by the Board of Lunacy and Charity as a single week's commitments would have overwhelmed us on the female side. For several months all patients have been sent to Westboro'. According to the terms of the law, and in practice, only homeopaths and paying patients are allowed to select their own hospital.

**A NEW SWISS PHARMACOPŒIA.**—A new Swiss Pharmacopœia is shortly to be published. A request has been sent, by the collaborators, to Swiss medical societies and practitioners, requesting suggestions as to the introduction of new remedies and the retention of old ones.

## THE PATHOLOGY AND TREATMENT OF CHRONIC SCIATICA.

*Read before the Section of Surgery and Anatomy, at the Fortieth Annual Meeting of the American Medical Association, at Newport, June, 1889.*

BY J. G. CARPENTER, M.D.,  
OF STANFORD, KY.

*Pathology.*—Chronic sciatica may be the result of the acute form, or may be chronic from the beginning and run a tedious, painful and protracted course—at times almost abating, to be again renewed with increased paroxysms of pain. It has been truly said of sciatica that "it is an unwelcome guest who returns when least expected." The points of greatest sensitiveness are the buttock, sacro-sciatic notch, post trochanteric line, head of fibula, outside of leg, maleolus, sole, outside and two-thirds of the dorsum of the foot.

There are two factors in the pathology of chronic sciatica, viz: one a neuralgia or neurosis, the other a neuritis or perineuritis, inflammation of the sheath and surroundings of the nerve trunk. The disease may be located in the peripheral or central portion of the nerve. Chronic sciatica may be the manifestations of a neurosis—functional derangement of a nerve centre found in neuropathic constitutions. There may be anæmia or hyperæmia of the nerve and sheath, or nerve centres, pressure of tumors, or a reflex irritation of the nerves from genito-urinary or rectal diseases as a urethral stricture, displaced uterus, or ovary, fissure, hæmorrhoids, pressure of the nerve by a contracting cicatrix, deposit of callus on the nerve or some of its branches, the rheumatic or gouty diathesis, spinal concussion, syphilis, malaria, pregnancy, over-lactation, alcoholism, venereal excesses, lead and mercurial poisoning, excessive fatigue, diseases of the vertebra, or pelvic bones, a damp or cold climate.

In the consideration of chronic sciatica, this question presents itself, viz: Is the pathological condition a neuralgia or a neuritis? In neuralgia of the sciatic nerve on ante- and post-mortem inspection, there have been no pathological lesions found in the nerve or its coverings; if the above causes were the only factors concerned in the pathology of chronic sciatica a removal of them *a priori* would cure the disease, but such is not the case; for though the cause may be removed the disease may still exist in all its obstinacy, and another factor must be considered, viz: a neuritis, or a peri-neuritis which makes chronic sciatica so rebellious to treatment. In chronic sciatic neuritis the pathological state is rather in the sheath of the nerve than in changes of the nerve fibres; the nerve fibres may undergo some pathological change in this condition, but what is at present known is, that the neurilemma or connective tissue sheath of the nerve, including its minute prolongations between and around separ

ate bundles of nerve fibrils, becomes much more hyperæmic than natural, and that on microscopic examination there is to be found in addition to the increased vascularity, a multiplication of new tissue elements and the presence of migratory leucocytes. These changes may cause considerable swelling of the nerve sheath and of its prolongations, and thus may produce irritation, or more or less compression of the nerve tubules, according to the amount of new tissue elements which accumulate in, or are produced within the sheath. In neuritis the nerve often appears to the eye normal, and the characteristic changes are only revealed by the microscope.

The microscopic changes in neuritis may extend to all the constituents of the nerve and present the ordinary picture of acute inflammation, hyperæmia, exudation, accumulation of white corpuscles in the tissue, and even the formation of pus. The nerve fibres, exhibiting in various degrees, the destruction of the white substance of Schwann and the axis cylinder, or, as in chronic neuritis, the alterations may consist in the more gradual proliferation of the peri- and endoneurium, which contracting renders the nerve dense and hard, and destroys the nerve fibres by compression. When the perineurium has been the principal seat of the inflammation in chronic neuritis, the trunk of the nerve becomes hard and thickened, from proliferation of the connective tissue. Sclerosis of the nerve.

In chronic neuritis as in the acute, the perineurium may be exclusively affected, the fibres remaining normal (Crushman and Eisinlohr). The nerve fibres themselves may be the primary and almost exclusive seat of neuritis, exhibiting more or less complete destruction of all their constituent parts, excepting the sheath of Schwann without hyperæmia, with little or no alteration of the interstitial tissues. Sometimes the fibres are affected at intervals, the degeneration occupying a segment between two of Ranvier's nodes, leaving the fibres above and below normal. (Neurite segmentaire periaxle). Gambault. "All of these lesions of the nerve fibres may be recovered from by a process of regeneration, the fibres showing a remarkable tendency to recover their normal structure and function. The nerve does not always present the appearance of a continuous inflammation, but the evidence of neuritis may be seen at points along its course which are separated by sound tissue. These points of predilection are usually exposed positions of the nerve or near joints."

"In chronic neuritis, the morbid anatomy consists of an increased vascularity of the affected nerve, sometimes of a varicose state of the blood-vessels, of a thickening and induration of the neurilemma in consequence of coagulate exudations. In variable degrees the nerve assumes somewhat of a slate color, loses its characteristic

opacity, and when examined under the microscope the nerve fibres are found to have fallen to a greater or less extent into a state of disintegration. The inflammation may attack the sheath of the nerve chiefly, and contract adhesions to neighboring tissues, the nerve itself remaining movable, although compressed. In other cases the nerve as well as the sheath is the seat of inflammation. In the growth of new connective tissue the proper nerve elements are compressed, and consequently atrophy and disappear, nothing remaining but a fibrous cord. On microscopic examination there is but little hyperæmia; the interstices are crowded with leucocytes and granular cells, but the most important change is the overgrowth of interstitial connective tissue, and the consequent fatty and atrophied degeneration of the nerve fibres with their axis cylinder; with injury to the nerve, occur secondary trophic changes."

Secondary trophic changes in chronic neuritis: The trophic changes dependent on chronic neuritis are frequently very prominent and important. Most commonly there is paresis, which may deepen into paralysis with atrophy of the muscles and degenerative reaction. The skin sometimes becomes rough and scaly, sometimes atrophied, smooth and shining (glossy skin). Edema of the subcutaneous cellular tissue is often seen. The hair of the affected part shows sometimes increased growth, sometimes it falls off. The nails may become thickened, rigid, and distorted. Deformity of joints with enlargement of the ends of the bones is not infrequently met with as the result of chronic neuritis. In short, we may meet with all of those trophic changes which have been described as arising from neural irritation, and which occurs in chronic neuritis as the result of compression of nerve fibres by the contraction of the proliferative connective tissue in the nerve trunk."

The diagnosis of chronic sciatic neuritis from chronic sciatic neuralgia cannot always be made, but the following conditions may be observed, viz.: That the neuralgia is generally dependent on some constitutional dyscrasia reflex irritation, compression of nerve by a contracting scar, a morbid growth, or a callus, and by removing the cause or disease on which the sciatica is dependent, the latter is ameliorated or cured; ante-mortem inspection of the nerve on exposure, may give no evidence of disease, and be considered neuralgic, though in obstinate cases it may be presumed there was a neuritis, or a perineuritis, or at least a hyperæmia of the nerve for the starting point. Heat, redness, swelling and pain are not absolute in neuritis as in other inflammatory affections.

There may be relative constancy of pain with the secondary trophic changes, spasm, atrophy, and paresis of the muscles, with atrophy and

coldness of the limb supplied by the nerve and conditions of causalgia, hyperæsthesia, paræsthesia, or anæsthesia with tenderness of the nerve along its tract together with the long standing of the disease; and in addition there may be organic nutritive changes affecting the skin, hair, nails, or the bones which would be diagnostic of neuritis or perineuritis.

The sciatic nerve being a mixed nerve, both sensory and motor. There will be two sets of symptoms in chronic sciatica. The sensory symptoms usually precede the motor, and are much more prominent for many weeks, months or years. The motor may be absent altogether. From the sensory there will be more or less continuous pain. At times paroxysmal, perceived at different points along the nerve trunk extending into its peripheral branches, and sensations of heat, cold, numbness and tingling sensations, hyperæsthesia, causalgia, or anæsthesia in the trunk or peripheral branches of the nerve. From the motor fibres there may be twitching and impaired functions of the muscles, amounting in many cases to spasms, or the motor fibres may be so involved as to cause paresis and atrophy of the muscles with impaired circulation, and nutrition with atrophy and coldness of the limb. Fortunately, for the victim of chronic sciatica many of the morbid states of both the motor and sensory fibres are absent. In most cases only a few having all the conditions enumerated.

Sciatica may extend centrally and involve the spinal cord. It is often quite painful or impossible for the patient to assume the sitting posture, owing to the extreme tenderness of the nerve trunk near the tuber ischii. Again it is impossible for the patient to lie in bed on the side of the affected nerve, or even on the back, owing to the great tenderness at the posterior inferior spine, of the ilium and fold of the buttock, unless the pressure of the bed is removed from the tender points by soft pads, or pillows placed under the knees and back, or the latter, and outside of the thigh.

There is an attitude and gait peculiar to the chronic sciatic patients, accurately described by M. Charcot in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, vol. xii, Feb. 16, 1889, No. 7, and he is the only writer, or authority known to the writer, who has given this description. In both of my patients who were nerve stretched the gait was quite characteristic. The first patient had chronic sciatica of the right sciatic nerve. The trunk was inclined to the left, the vertebral column described a curve with its convexity to the right, the left hand descended much lower than the right, the right lower extremity was semi-flexed, the buttock of this side presented a flattened appearance, the gluteal fold being elevated; finally the heel of the right foot did not touch the floor (Charcot attitude). The limb was atrophied and cold, one inch and one

half smaller from hip to foot than the left, and patient was unable to sit on the right buttock. The condition of the nerve on exposure before stretching was this: The neurilemma was found to be thickened, congested, and numerous reticulations of small blood-vessels ramified in the sheath; the latter, had lost its opacity, and was of a pinkish yellow color, had many nodular deposits, and had many adhesions to the adjacent tissues, showing plainly that the case was one of chronic sciatic perineuritis. Attitude of second case, left sciatic nerve affected, the trunk was inclined to the right, the vertebral column described a curve with the convexity to the left, when the pain was great or recurred in paroxysms, the left lower extremity partly flexed, except when walking on the street the buttock of this side presented a flattening, the gluteal fold being elevated, the heel of left foot did not touch the ground, or floor, without pain in the thigh. In the recumbent posture the left limb was flexed, pads or pillows had to be placed under the knee and back to remove pressure from the tender points, otherwise the patient could not lie on the back or left side; the limb was one and one-half inches smaller from hip to foot than the right one, and cold and atrophied, and patient was unable to sit on the left thigh and buttock. The pathological state of the nerve found on cutting down upon it and exposing it, were some fibro-cystic tumors and nodular deposits on the nerve (perineuritis nodosa chronica), and bands of lymph and adhesions. Between the sheath and adjacent tissue the neurilemma had lost its normal appearance and showed signs of fatty degeneration, and was traversed by many small blood-vessels. This was also a case of chronic perineuritis. Both of these patients had the hyperæsthesia of the skin in which touching, or brushing the affected parts causes a peculiar, disagreeable, nervous thrill, from which the patient shrinks, but which, however, is not a pain.

The treatment of chronic sciatica may be medical, mechanical, electric and surgical. It is presumed that tonics, restoratives, alteratives, and all other constitutional measures have been given a thorough and faithful trial, and that the condition, or disease on which the chronic sciatica was dependent has been removed or cured, and that such local measures as the employment of morphine, chloroform, sulphuric ether, osmic acid, atropin, cocaine, ice-water, antipyrin, and spraying locally with sulphuric ether, chloride of methyl, or rubbing the nerve tract with menthol or aconitia ointment, or ice, the free use of blisters, the hot or cold douche, massage, electricity, and actual cautery have been used, weighed in the balance, and found wanting, before the numerous surgical procedures are resorted to.

The local application of the actual cautery over the bed of the nerve, at three to five points,

at intervals of two to six inches, frequently ameliorates the condition of the patient, or cures the disease. The cautery iron, the paquelin cautery, or a glass rod heated to a white heat, over a spirit lamp, and applied in quick succession at points two to six inches apart, is preferred by the author. The latter does not blister, nor cause a running sore, but makes a dry burn of the integument, and is equally as effective as the other canteries. Sulphuric ether or chloroform, at first seem to have a counter-irritant, than an anodyne effect when inserted into the bed of the nerve, and should be used in drops ten to thirty daily, or two or three times a week. The local use of morphine, atropin and cocaine, is much enhanced by combining one or more of these agents with one or the other of the drugs.

Graham speaks very highly of massage in the treatment of chronic sciatica, and gives a number of cases of several years duration—one case extending over nine years. Not only is it highly essential to the neuralgia or perineuritis, but it arrests and prevents secondary trophic changes; it increases the circulation, nutrition, and growth of the limb, and is anodyne besides.

Before cutting down and laying bare the nerve trunk to stretch, or even to perform Nussbaum's bloodless nerve stretching for the relief of pain, or any other purpose whatsoever, massage should be thoroughly tried, as the action of this method is somewhat similar to that of the other, releasing the nerve from neighboring tissues that compress it, and producing changes in its structure and circulation, and lessening its irritability, perhaps, by over-stretching. Massage and mild stretching might succeed when more violent stretching would fail. Langenbeck makes use of massage in the vicinity of the wound, after the violent stretching by surgical operations. In both of the writer's cases which were nerve stretched, massage had been given a faithful trial, and all other milder procedures, before resorting to nerve stretching. In the early and late stage of neuritis, massage is indicated; in the early it would act as a prophylactic, relieving congestion by causing a free circulation in the surrounding tissues, and by pushing the blood out of the distended vessels. In the late, by causing absorption of inflammatory products, the repeated mechanical effect of manipulation and percussion upon old neuralgia benumbs and lessens the sensibility of the neural filaments, and gradually decreases it, hence its use in chronic sciatica; not only may pain be relieved, but states of hyperæsthesia, paræsthesia, causalgia and anesthesia are relieved by massage, in addition to massage inunctions of vaseline, or olive oil are indicated in the secondary trophic changes of chronic sciatica. Massage should be used by gentle stroking, firm pressure, and slow, deep kneading. Acupuncture in chronic sciatica is a

valuable remedy, as well as in lumbago and other neuralgias, and rheumatic affections. Patient is laid upon the face, the tender points are found, and one or more needles inserted from half to one and a half inches, and allowed to remain from a half to two hours. The number of needles used is from one to six. In sciatica the needle should actually penetrate the nerve. This is known by the patient complaining of a sudden, sharp, shooting pain down the back of the thigh; this action may be due to the escape of nerve fluid, also to its counter-irritant effect. Cocaine may be used hypodermatically in connection with acupuncture.

*Electricity.*—The galvanic current has the precedence over the faradic, in relieving neuralgia, and also in chronic sciatic neuritis. It causes better nutritive and functional changes in the nerves and nerve centres, and causes restoration from many morbid conditions of the sensory fibres. The faradic is, perhaps, better indicated in the secondary trophic changes of chronic sciatica neuritis, affecting the motor fibres. Electricity has an anodyne effect and relieves the accompanying neurasthenia. It makes little difference whether the anode or cathode is used in the neighborhood of the nerve. The direction of the current is of no material importance.

*Treatment.*—In addition to acupuncture, the following surgical measures may be resorted to when other means have failed. Brown-Séquard has recommended exposure of the nerve and washing it in ether to effect the same end as nerve stretching. Nussbaum recommends bloodless nerve stretching in sciatica, which consists in having the patient etherized, whereupon the thigh is forcibly flexed on the pelvis, and then the leg extended on the thigh, and the foot on the leg—dorsal flexion—and held for a short time in this position. A considerable degree of stretching of the sciatic nerve is possible—in this way, a number of cures have been made—though less dangerous than stretching the exposed nerve, it is no trivial operation. The effects of nerve elongation are these, viz: Central elongation affects sensation, and peripheral mobility, direct and reflex excitability of the nerves disappear under the influence of strong traction, and is increased under limited traction. Sensibility is increased at first, and disappears more or less completely and more or less permanently according to the force employed and duration of the time of traction. Sensory fibres lose their excitability before the motor fibres. (Baum and Nussbaum). Mobility is less influenced than sensibility, and is reestablished by slight elongation.

*Modus operandi of elongation.*—This is considered by some neurologists to act by diminishing the conductivity of the nerve, others by freeing it from adhesions, of pathological sources of compression. As regards function, nerve

stretching has but little influence on mobility, and when well performed is never followed by persistent paralysis; on the contrary, a permanent anæsthesia is indispensable to its therapeutic action. When it is directed, as is most frequently the case, against an exaggeration of the direct, or reflex sensory—motor irritability of the nerves.

Most nerve stretching has been done for neuralgia, especially sciatic neuralgia, giving more successes than on other nerves, and for other affections. Should the first operation of nerve stretching not succeed, a second one may be done after a reasonable length of time. Prof. H. B. Sands, of New York, has done nerve stretching the second time for chronic sciatica on the same patient, having performed the first about six months previous to the last. A degree of contraction may follow a rheumatic, or gouty deposit in the nerve sheath, and thus affect the nerve current in the centre of the fibre, which may be drawn out by the nerve stretching, the normal function of the nerve tubule being thus restored temporarily or permanently. The success may be owing to an alteration in the relations between the nerve fibres, having the effect of improving their nutrition. (Nussbaum). Nerve stretching is a less serious operation than nerve section, and more efficacious, and should be done in preference to the latter in chronic sciatica.

Indications for nerve elongation are, first, violent pain; second, continuous and annoying hyperæsthesia, paræsthesia, or causalgia; third, anæsthesia; fourth, paresis and atrophy of the muscles and limb to cause nutritive changes. Mild traction on the central end of the nerve, for sensation, and the distal end for mobility; fifth, the prevention of structural changes in the spinal cord; sixth, it may be used as a *dernier ressort*.

Nerve stretching is effected by cutting down upon the nerve trunk, detaching it from its connections for the space of a few inches, laying hold of it with the fingers, forcibly stretching the whole nerve from its origin to such an extent as to affect powerfully its functions, and then closing up the wound. In some instances a certain amount of loss of sensation or muscular power in parts to which the nerve is distributed is the immediate result, which, however, passes away after a certain interval, and the nerve function becomes more or less completely restored. When the sciatica is due to the pressure of tumors, or neuromata in the nerve tract or neighborhood, in addition to removing the tumors, the nerve may require to be stretched on account of its diseased condition, and the operation would not be complete unless the nerve was elongated.

From ten to thirty or forty pounds traction on the nerve is required; the amount of traction depending upon whether it is for the relief of pain, anæsthesia, hyperæsthesia, or to increase the mobility and nutrition of the limb. Rupture of

a moderately large nerve is not to be feared, since Baum has proven it is impossible to employ a force of more than 33 lbs. av. in making extension with a grooved director.

The pathological anatomy of nerve stretching consists in a laceration of the sheath, and in rupture of the blood-vessels which are distributed to its interior.

Schliech says a coagulation of myelin occurs; Tarchanoff says immediately after elongation traces of hyperæmia and capillary hæmorrhage and the division of a certain number of nerve fibres of the myelin and axis cylinder are found; the sheath of Schwann always remaining intact. Scheving found healthy fibres, especially at the centre of the nerve, and fibres in a state of fatty degeneration. In fine, nerve stretching seems to cause most frequently the rupture of a certain number of nerve fasciculi. Forcible elongation of large nerves does, sometimes, affect even the spinal cord. Sequelæ of nerve stretching are sensory or motor paresis, one or both, depending upon the amount of traction employed. If forcible traction on central end of nerve trunk has been exercised anæsthesia results; otherwise, hyperæsthesia. By slight traction on the distal end motor paresis or chronic sciatica may be relieved or cured. To control spasm of the muscles supplied by the sciatic nerve, forcible traction will produce paresis. Rigors within an hour after the operation of nerve stretching frequently occur. Should insomnia and neurasthenia not precede the operation they will attend it. Retention of urine for a few hours may supervene.

The treatment of patient after the operation is of great importance. It is desirable to get primary union of the wound in order to avoid the formation of a cicatricial tissue and compression of the nerve after the operation. For the first few days after the operation the limb should be kept extended at rest, and bandaged from the toes above the wound. After the seventh or fourteenth day passive motion and massage should be applied to the limb and affected muscle supplied by the nerve, to prevent adhesions and further degeneration and atrophy of the nerve, muscles and limb. The limb should be bandaged from three to six weeks to prevent œdema, to support the groups of muscles, and to prevent stretching of the scar, and to hold the limb in normal position until the nerve is regenerated, and the limb restored to its normal state. Sayres' artificial rubber muscles, a splint, or a removable plaster-of-Paris boot may be necessary to hold the limb in its normal position and prevent torsion and extension of the foot inwards, until the temporary motor paresis is cured. During the convalescence of most cases anodynes, soporifics and nerve tonics will be indicated. Exercise in the open air and sunlight on crutches, and in the wheel invalid chair, are highly essential, and should be employed with consistency.

In many cases it may be necessary to use local and general electricity, or both, to hasten the recovery of the motor paresis and the secondary trophic changes, and counteract and relieve the neurasthenia that generally accompanies the chronic sciatica before the operation, or which usually follows it.

The success of nerve stretching: In chronic sciatica, in 168 cases collected from various sources 153 have been cured, 15 cases temporarily benefited. In other neuralgias, out of 189 cases, 132 have been cured, and 33 permanently benefited. Bryant gives 70 operations of nerve stretching for sciatica; statistics indicate that in 60 the patients were either cured or greatly relieved, and that in the majority of cases the relief was permanent. The writer is informed that Mr. Calendar and other English surgeons have had about 60 per cent. of recoveries from nerve stretching.

As an extreme measure and a last resort, nerve section has been done for chronic sciatica and other neuralgias. Nerve resection has been done by Sapolino, Brinton, Morton, Hodge, Vance, Golding-Bird and Wyeth with at least temporary benefit. Cures have been reported of neuralgia that was cured by resection when nerve stretching had failed.

## THE ORIGIN OF PUS.

*Read in the Section of Dental and Oral Surgery at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY WM. ATKINSON, M.D.,  
OF NEW YORK.

It is the gift of genius to foresee discoveries even for centuries. Such a genius was John Hunter, of London, who toward the end of the last century, merely upon the ground of speculation and ratiocination, made the assertion that inflammation is nothing more than a return of the tissues to embryonic condition. And our present knowledge of the process of inflammation and suppuration is a strong proof, supported by careful researches of good pathologists of Germany and England, that Hunter's theory was the correct one.

Since microscopy became a science (a period covered by half a century) the views concerning the intimate nature of the inflammatory process have been greatly at variance. These views largely depend upon the general ground taken by pathologists in reference to the pathological processes at large. We have three marked phases in the development of pathology within the last fifty years. The first is the standard of humoral pathology promulgated by the late Rokitsansky, of Vienna. The second is the phase of cellular pathology established mainly by Virchow, of Berlin. The third phase, still in vogue with many pathologists, is the doctrine of emigration of colorless

blood corpuscles or leucocytes, as propounded by the late Cohnheim, of Leipsic. I personally went through all these phases and am willing to admit that each meant progress, and still I have grown old enough to convince myself that neither of the views mentioned contained the whole truth. I have witnessed researches going far to prove that it is mainly a combination of the previous views that makes us approach the truth. I say approach, for there is no reason to deny that coming decades will bring us forward still more in our understanding of the intricate nature of the process termed inflammation and suppuration. During the past five years bacteriology has held sway of the minds of the majority of the pathologists, proving what was just stated. To-day no one will be rash enough to neglect the influence of bacteria in producing suppuration. And have we not learned through excellent observers that it is not the microorganisms themselves, but rather their chemical products, the ptomaines, that play an important rôle in the causation of suppuration and possibly of inflammation. I here allude to the latest researches of Seber, of Goettingen, who maintains that it is a ptomaine, called by him *phlogestein*, that stands in causal relation to inflammation.

The task I have undertaken is to bring before you a review of the theories held in the last fifty years, closing my historical remarks with a description of what I consider to be the truth to-day. The review of such a history is instructive in many respects. It teaches us that none, be he of the most gifted talent, is able to emancipate himself from preconceived ideas and accepted notions. It furthermore teaches us that we are the subjects of general theories extant for the time in which we make our investigations. It teaches the great lesson of modesty and humility. If a man of my age must confess in the seventh decade of his career that he has been misled in his younger days by books and teachers and must try hard to unlearn what he thought he knew before, it is certainly proof of human frailty, and goes far to prove that we are obliged to consider the truth to be truth only *pro tempore*, viz.: so long as we do not know better. Our successors will surely step over our shoulders and will estimate our work only by considering the amount of time, honesty and acuteness of mind spent in bringing forth new facts and new revelations.

In the fifth decade of our century humoral pathology was thought to hold the full truth in the explanation of inflammation. The older of us will remember which facts the humoral pathology was based upon. The web of the foot of a living frog was expanded over a cork ring and the web touched with an irritating agent, such as a drop-let of ammonia, an acid, or with a pointed, red-hot iron, and the subsequent changes observed under the microscope with the comparatively low powers

at the disposal of investigators of the time. They saw around the irritated portion of the web an undulation of the currents of the blood within the vessels, shortly afterwards a slacking of the current, and still later a standstill of the stream. The last phenomena they called "stasis," and this stasis was thought to be the essential feature of the inflammatory process. Many and animated controversies arose over the question, what is the stasis due to? Most observers agreed that a paralysis of the capillary blood-vessels, after a few preceding contractions, was to be considered the cause of stagnation. At the same time an inundation was seen to take place in the affected tissues with a liquid which of necessity must have come from the general blood column, and was termed "exudate." According to the nature of the exudate different varieties of inflammation were set up, such as the "serous," the "fibrinous," the "albuminous," and should blood have been admixed with the exudate, the "hæmorrhagic." Corpuscular elements seen in the affected territories and apparently suspended in the *exudate* were thought to have originated from the exudate itself, therefore the pus corpuscles would have originated from the exudate, the latter from the blood, hence the definition of pus, "dead blood." No stress was laid upon the structural changes of the affected tissue itself, except so far as the exudate saturating this tissue was concerned. The ultimate cause of inflammation and suppuration was sought in chemical mixtures of the blood, termed dyscrasia, which means bad mixture of the blood. If a person became affected with lobar pneumonia the cause surely was surplus of fibrin in the blood, or fibrinous dyscrasia. If a person produced a number of abscesses in his organism the cause was denominated purulent dyscrasia. All diseases were, in this dyscrasic view, essentially diseases of the blood. The blood in its mixture caused the diseases simply by being overloaded with obnoxious or effete material.

The man who dug the grave of humoral pathology was Virchow, in the beginning of the sixth decade of the present century. To him the phenomena of alterations in the circulation of the blood were of secondary importance. The stasis he would not admit as a cardinal symptom of inflammation for it would mean rather death of the tissue, gangrene or necrosis. The exudate also played but a secondary rôle, serving only as a pabulum to the living corpuscular elements of the tissues, the so-called *cells*. Inflammation was, in Virchow's opinion, a structural change of the affected tissue, mainly morphological changes of the cells themselves. The cells being the seats of life would attract and, as it were, imbibe the exudate, swell up, divide and come to a state of proliferation, in which a number of cells would arise from an original single cell, and the large number of newly-formed cells would replace the intercellular

substance lost by liquefaction. A formation of cells out of a previous liquid or semi-solid exudate was declared to be impossible, since all newly-formed cells must have arisen from preëxisting cells. Dyscrasias were done away with. The main causes of inflammation were peculiarities of the tissue itself, and a certain weakness of the tissue was proposed to explain the predisposition to inflammatory processes. The word suggested for this supposed local weakness of the tissue was "diathesis." If a man suffered from articular rheumatism the cause was said to be "rheumatic diathesis." Tuberculous persons were predisposed to cheesy degeneration simply because they were afflicted with *tuberculous* diathesis. In the same sense hæmorrhagic purulent diatheses were spoken of. The pus corpuscles were without exception an offspring of the previous cells of the tissue, and in this sense pus was considered dead tissue. Cellular pathology has made a very strong impression on the minds of observers. Even the stalwart humoral pathologist Rokitsky yielded to the novel views and accepted the doctrine that no cell will grow in an exudate unless previous cells be there. Cellular pathology even in our day governs the minds of most pathologists over the civilized world. Proliferation of the cells accounts for all tissue changes, either newly-formative, the so-called hyperplasia, or destructive, that is, suppuration. Proliferated cells being present in either of these instances, cellular pathology is at a loss to explain why a certain tissue, owing to proliferation of its cells, becomes augmented and hyperplastic in one instance and is destroyed by suppuration in the other. Still, in spite of all weaknesses of this doctrine, we must consider it an advance in comparison with the teachings of humoral pathology. The cell being supposed to be the only center of life, inflammation and suppuration were for the first time considered as the phenomena of life, and the idea began to dawn in the minds of pathologists that inflammation and suppuration were morbid processes occurring in tissue elements endowed with life, the so-called cells.

The third period arose in the middle of the seventh decade of our century, when Cohnheim observed a migration of colorless blood-corpuscles through the walls of the capillaries and small veins of an exposed and expanded mesentery of a frog. Several years before S. Stricker, in Vienna, observed the red corpuscles pass through the walls of the capillaries of the nictant membranes of the live frog, so-called diapedesis. Even in 1848 the emigration of leucocytes had been seen in England by Walker and Wallace. The facility with which the emigration of leucocytes could be seen under the microscope has induced many German pathologists to accept the view of Cohnheim, that inflammation and suppuration are but an emigration of colorless blood-corpuscles.

These accumulating in a tissue whose cells would remain inert and whose intercellular substance would become liquefied and destroyed, furnish a representation of both inflammation and suppuration. With this view there was nothing alive in the body but the leucocytes. At first Cohnheim denied the participation of the so-called stable cells in the process of inflammation, but later he admitted that in reparative inflammation the tissue cells do proliferate and furnish their share for the benefit of newly-forming tissue, exactly in the sense of cellular pathology. That pus corpuscles should be emigrated colorless blood-corpuscles was intelligible, as were isolated corpuscles nearly identical in appearance. How new tissue could form from leucocytes remained a deeply-shrouded mystery, as no observation has as yet proved that through coalescence of leucocytes new protoplasmic masses and new tissues can arise. The observation of Zeigler, of Tübingen, that multinuclear bodies, so-called giant cells, are invisible between thin glass plates introduced under the skin of an animal lacks the proof that such giant-cells arose by coalescence of leucocytes. On the contrary, later observations made especially upon deciduous, replanted and implanted teeth, go far in proving the giant-cells to be an offspring of the myxomatous granulation tissue, sprouting in all directions, filling the bay-like excavations on the deciduous and other teeth and carrying blood-vessels into places where there had been none before, leading to the vascularization of a new tissue, seen, for instance, in sponge grafting.

S. Stricker immediately sought to overthrow the teachings of Cohnheim. In his investigations he used almost exclusively the cornea (chiefly of frogs, cats and rabbits); in which he brought inflammation by introducing a thread. The changes were faithfully watched up to the formation of abscess around the foreign body. The observations enabled him to prove the established views of cellular pathology to be correct, namely, that these so-called cells divide and subdivide, but also that the coarser offshoots of the cornea corpuscles split up, and by division produce new corpuscular elements. Stricker also held, up to 1874, (Ashurst's *International Surgical Cyclopædia*), that pus corpuscles were products of proliferation of the cornea corpuscles and their coarser offshoots. Unfortunately he calls all the products of cells originating from proliferation of previous cells pus corpuscles. Indeed it was impossible to discriminate between inflammatory corpuscles and pus corpuscles, since all of these appeared isolated under the microscope. Clinically it is well established that every inflammation does not terminate in suppuration. Particularly do we know of a termination which instead of causing destruction of an affected tissue, as suppuration does, brings about a new formation, an increase

of the bulk of the tissue, the so-called hyperplasia. How shall we explain such marked differences by the theory of cellular pathology, which claims all corpuscular elements are isolated from the start? However, since 1880 Stricker is a convert to the views of C. Heitzmann, established in 1873, which doctrine I advocate, having studied specimens, illustrative of inflammation and suppuration, under the microscope in that investigator's laboratory.

Let us recapitulate in a concise way the views held by the said C. Heitzmann concerning the normal or physiological structure of tissue. He holds that there is no isolated or individual cell in any variety of tissue in either the animal or vegetable organism. Such individual corpuscles are met with only in the fluids of the body, such as the blood, where they are named red corpuscles; in the lymph, called lymph corpuscles; in the saliva, called salivary corpuscles; in the sperm, called spermatazoids, etc. Neither the blood nor the lymph, nor any of the fluid, semi-solid secretions deserve the name of a tissue. Tissue we call a continuity of not only organized material, but a material endowed with all the properties of life, such as mobility and the capacity of reproduction. Tissues hold at certain intervals protoplasmic bodies, so-called cells, the vast majority of which are in continuity with the living matter held by those substances, previously termed "intercellular" and to-day they are known by the names of basis and cement substance. The greatest amount of living matter is present in the centers of protoplasmic bodies, where they appear as nuclei and nucleoli. The surrounding protoplasm, in full development, holds the living matter in a reticular arrangement and such a reticulum is traceable throughout the surrounding basis substance, hitherto considered as entirely inert. Thus an uninterrupted connection is established from one "cell" to another by the intervening bridges of living matter. This same arrangement being present throughout all tissues of the animal organism, a continuity of all the tissues composing such organism is established. Recent researches of botanists go far to prove that even in the plants there exist no individual cells, but the intervening cement substance, or cellulose, is traversed by minute bridges of living matter, rendering the plant an individual from the tips of the leaves to sporacles of the rootlets. Recent observers in animal and vegetable microscopy have drawn attention to the fact that by means of certain reagents the nucleus will be split up into loop-like threads, a process which they consider precedes the division of the nucleus and indirect division of the protoplasm. This process is termed karyokinesis, or mitosis—"fibrillation," "thread making." This observation is had only with certain reagents and is not visible in the fresh specimen or in one preserved in a chromic

acid solution. Suspicion naturally arises that the loop-like figures of the nucleus are artificially produced and thereby their connections are rendered invisible. The threads forming loops are called "chromatin," because readily stained by aniline dyes, whereas the intervening substance and the protoplasm itself stain but little, and therefore are "acromatin." Facts rendered conspicuous by staining appliances only are of doubtful correctness. The fact that there are threads and loops in the star-point form arrangement in the nucleus rather proves the latter to be made up largely of living matter, which is known to change shape any moment. Coarse formations of living matter readily stain with aniline dyes, whereas delicate formations of the same substance will not stain. The connections between the loops of the nucleus and the surrounding radiating reticulum of the protoplasm are plainly visible in fresh specimens, and also those preserved in liquids which we know will not alter the structure of protoplasm, such as a solution of chromic acid of one-tenth to one-half of 1 per cent. Alcohol as a preserving fluid is far inferior, owing to the shrinkage it effects.

Let us analyze the construction of dentine (most important to dentists, since it builds up the main mass of the tooth) in the light of this novel doctrine, for which the late Louis Elsberg, one of its most enthusiastic advocates, suggested the term bioplasson theory. Dentine has no cells, but is composed of a dense, firm basis substance (not cartilaginous as formerly thought but glue yielding, similar to that of bone tissue) thoroughly infiltrated with lime salts. This basis substance is traversed by the canaliculi which radiate from the surface, occluding the pulp chamber toward and join the cement and enamel. Each canaliculus holds in it a delicate fibril, the so-called Tomes fibre, around which exists a minute space filled with a liquid, obviously the carrier of nutrient and denutrient substance. Fine thorn-like offshoots were known, especially in transverse sections of dentine, to emanate from the fibril, traverse the surrounding space and fade upon approaching the wall of the canaliculus. Now in the light of the bioplasson doctrine the Tomes fibres are formations of living matter. From them arise transverse conical offshoots penetrating the walls of the canaliculi and in connection with a delicate, nearly rectangular reticulum traverse the whole of the basis substance and connect the tenant of one canaliculus with the neighboring tenants directly, and therefore all the others indirectly. The presence of this reticulum was first established by C. F. W. Bödecker, in 1878, who saw light rents in the basis substance and assumed them to hold living matter without being able to directly prove its presence.

This proof has been quite recently furnished by Wm. Carr, who after decalcification of the dentine

by means of a 6 per cent. solution of acetic acid rendered the reticulum visible by staining with a chloride of gold solution, and also osmic acid. These last results have not as yet been published by their observer. I have seen his own specimens through lenses of 1,000 to 1,200 diameters with good immersion, and am convinced of the presence of the reticulum throughout the dentine.

Thus we understand how dentine can grow and be nourished, and realize it is a tissue endowed with sensibility prominently at those places which abound with living matter, such as the periphery toward the enamel and the cementum at the neck of the tooth. Therefore we can appreciate that living dentine, if irritated by a foreign body, such as a mass of gold filling, or chemically by acids, will react upon this injury, become inflamed and produce a new tissue, called osteo-dentine, which sometimes is more compact than the original. This process of the inflammation of the dentine, called "eburitis," was carefully studied by Dr. Bödecker a few years ago, and although he has not yet completed his studies upon teeth which had been filled with different materials for months and years, every intelligent dentist knows that such a reaction exists. This fact is utilized by all of us in introducing highly-irritant agents, such as oxyphosphate of zinc, into otherwise poorly calcified, so-called soft, teeth. The result after some months is a compact wall of the cavity made up of osteo-dentine, or secondary dentine, and better fitted to tolerate a gold filling than it was before this temporary filling. How can we understand these changes and the toleration of highly conductive filling, unless the tooth substance be a veritable living tissue throughout its extent? Whenever irritation is brought to bear upon a living tissue reaction will follow, and this is inflammatory process. The first that occurs is liquefaction of the basis—or cement—substance, probably induced by the presence of an acid, mainly lactic, thus the living matter previously concealed (held) in the basis—or cement—substance becomes liberated and the protoplasmic form of the basis substance reappears. This condition has directly been observed by S. Stricker on the cornea of frogs, as before stated. He saw the basis substance in motion, changing the configuration of its living matter, under the microscope, much like clouds changing on the face of the sky. Next the protoplasm furnishing the substratum of previous basis substance becomes split up into small bodies, known as medullary, or embryonal, or inflammatory corpuscles. Any portion of living matter of such indifferent bodies may grow to the size of a nucleus, owing to the presence of an excess of pabulum beyond the physiological requirements of these bodies, an excess essential to the inflammation. Not only the original "cells," but the intervening basis substance will participate in the formation of new

elements or inflammatory corpuscles. Here is the distinguishing feature between modern and antique pathological views, for according to the latter only the "cells" themselves were considered active and capable of proliferation. The sum total of the newly-formed inflammatory corpuscles is known under the term inflammatory infiltration, which means that a certain amount of a tissue, be it connective, muscular or nerve tissue, is replaced by and transformed into newly-appearing protoplasmic bodies in the stage of indifference, that is, being purely protoplasmic tissue bodies without any distinctive character either as to origin or destiny. So long as the inflammatory corpuscles remain in continuity by their delicate offshoots they represent a tissue, though in a condition of indifference, or embryonal state. Such a tissue by new formation of a basis substance will either return to the previous normal state, terminating the inflammatory condition in "resolution," or, being considerably augmented itself, will produce a tissue much greater in bulk than the one originally inflamed and we will have hyperplasia. In neither instance will the inflamed tissue cease even for a moment to be tissue. The tissue which is the bearer of the blood and lymph vessels is the connective tissue, and connective tissue is the only bearer of these vessels. And here is the starting point of inflammation in almost every instance. This we understand from the fact of the rather low dignity and activity of the connective tissue. We look for the greatest reaction on irritation at the sources of nutrition, obviously the blood-vessels. Muscle, nerve and epithelial tissue react in rather a secondary manner on inflammation of connective tissue. Virchow proposed the name "parenchymatous inflammation," for the designation of the inflammatory process, which term may be retained if restricted always to a secondary manifestation upon the primary inflammation of the "interstitial" connective tissue. A gland, for instance, is a compound organ composed of parenchyma according to Virchow, which is the epithelial glandular tissue. This is surrounded with and accompanied by connective tissue bearing many blood-vessels. It is impossible that the glandular tissue could be the primary seat of the inflammatory process. This process will be present in the connective tissue first and more or less rapidly invade the glandular epithelial tissue. If the connections of the inflammatory corpuscles be severed we shall have a certain number of isolated medullary or embryonal corpuscles suspended in an albuminous liquid.

Pus is therefore the resultant of destroyed tissue, but quite unfit for the production of any form of tissue. How much the emigrated blood corpuscles contribute to the formation of pus may not yet be positively stated. However, we do know positively that upon the approach of suppuration

in a certain tissue its blood-vessels are destroyed without exception in the territory involved. The blood-vessels, by outgrowth of their endothelia, become at first solidified and afterwards split up into medullary and pus corpuscles, the same as all the other elemental constituents. Even the smooth muscles of an artery will partake in this pus-forming process. The amount of migrated leucocytes cannot be great, considering the loss of the vessels which have supplied them. Pus is destroyed tissue, first originating in a closed cavity bearing the name of "abscess," or, secondly, coming from the walls of physiologically shut cavities, termed "empyema," or, thirdly, springing from exposed tissue surfaces, viz., such as granulating surfaces of wounds, termed "pyorrhœa." In the two latter instances, namely, empyema and pyorrhœa, the emigration of colorless blood corpuscles plays a far more important rôle than in the case of "abscess." In granulating surfaces of wounds, especially, the source of the pus corpuscles must be sought mainly in the capillaries, which abound in the myxomatous granulation tissue, producing loops therein, upon the grouping of which depends the raspberry look of the so-called "proud flesh." Around an abscess a dense layer of fibrous connective tissue is formed very soon—beautifully displayed in alveolar abscess at the apices of diseased roots of the teeth. This newly-formed layer represents the productive activity of inflammation, being hyperplastic, fibrous connective tissue, more or less well supplied with blood-vessels. Old pathologists termed this layer "*membrana pyogena*," which signifies that the membrane itself produces the pus. This view was abandoned long since, and to-day the *membrana pyogena* is known to be a secondary formation in the appearance of an abscess, as it were, a protective wall to the healthy tissues. After the evacuation of the pus from an abscess or an empyema, either by spontaneous rupture of the covering layer toward the surface, or artificially by knife or caustic, the *membrana pyogena* changes its character and becomes the seat of an acute inflammation, which leads to the formation of a freely-vascularized myxomatous tissue. This is what is called "proud flesh," or granulation tissue. In all instances in loss of tissue by suppuration the final result is the formation of a scar. This consists of a dense fibrous connective tissue whose bundles freely interlace and which is, as a rule, scantily supplied with blood-vessels. It is an outcome of myxomatous granulation tissue and is covered with epithelium whenever the pus has been discharged through the skin or a mucous membrane, which themselves appear in a normal condition with an epithelial layer.

Pus, therefore, is a tissue disintegrated and broken up into indifferent or medullary corpuscles which are suspended in a liquid more or less

rich in albumen. How much the emigrated leucocytes share in the formation of pus corpuscles may not be determined. The pus corpuscles remain alive as long as the liquid surrounding them is sufficient for the support of their nutrition. Even fatty degeneration of the pus corpuscles, as seen in chronic abscesses, will not altogether deprive them of their vital phenomena, such corpuscles, if transferred upon a slide, remain amœboid, and they die only by exposure to a low temperature, or after the addition of chemical reagents, or within the body by being deprived of their nourishing liquid. The last condition is noticed in cheesy degeneration of the pus so often met with in tuberculosis. A question now arises. What is the cause of the formation of pus? Ever since the famous experiments of Cohnheim and Counselman, who introduced vials filled with croton oil under the skin of rabbits, with antiseptic precautions, and after healing was complete cracked the vials, subcutaneously, thus producing an abscess, this is a much mooted question. A host of experimenters who have repeated these trials have taken views pro and con of the question. I consider the experiments of P. Grawitz and W. de Bary, published in Virchow's Archives, 1887, the most valuable testimony towards settling this question. They found that the subcutaneous injection of concentrated solution of chloride of sodium in rabbits and dogs was followed by cedema, a swelling of the facia, but no suppuration. It makes no difference whether the solution be mixed with a large number of staphylococci. Staphylococcus, with its three varieties, the staphylococcus pyogenes, aureo-albus and citreus, first discovered by Rozenbach, was thought to be essential to the production of pus. And even H. Knapp, of New York, maintained that a small quantity of Croton oil mixed with olive oil will not produce suppuration if introduced into the anterior chamber of the eye of the rabbit, whereas the same mixture if contaminated with pure culture of staphylococcus aureus will invariably be followed by suppuration under like circumstances. Grawitz and de Bary, on the contrary, have proven that not only the coccus named, but certain irritating reagents and different products of microorganisms, not necessarily the staphylococcus, different alkaloids, or ptomaines, are productive of pus. Solutions of nitrate of silver, if injected under the skin of dogs, rabbits, rats and mice, will be harmless if weak, not stronger than .005 of 1 per cent., but when 5 per cent. in strength will invariably be followed by abscess in dogs. Neither acids nor alkalies cause suppuration, except the liquor of caustic ammonia, which if introduced in full strength is followed invariably by suppuration. In neither of these instances were there any microorganisms discoverable in the pus freshly removed from the abscess, or transferred upon nutritive gelatine as a culture

medium. Oil of turpentine in rabbits and guinea pigs did not induce pus, even though injected in large quantities, but only inflammation; whereas in dogs oil of turpentine, which is a strong germicide, after subcutaneous injection was always followed by suppuration.

From these experiments it follows that chemical substances entirely free from bacteria and cocci tend to induce the suppurative process in different animals. On the other hand it was experimentally proven that in dogs and rabbits the injection of cultures of staphylococcus into the normal subcutaneous tissues will not induce inflammation or suppuration. It is necessary that a tissue first be irritated to a condition of inflammation, by traumatism or by chemical irritants, to have a soil favorable for the development of staphylococcus, which under these circumstances will produce an abscess. Lately P. Grawitz has shown that the subcutaneous injection of a ptomaine derived from putrescent organic material, called cadaverine, will always lead to the formation of an abscess. From the practical standpoint it is of the utmost importance to work aseptically, or in other words, with such degree of cleanliness that the introduction of microorganisms or their ptomaines becomes impossible. It is well established that even open fresh wounds if aseptically dressed with gauze saturated with a 1:1000 solution of corrosive sublimate and left alone for a few weeks will kindly heal without one single droplet of pus. Corrosive sublimate and carbolic acid are still most reliable germicides. We are not yet prepared to assert that microorganisms alone cause suppuration, since there are irritating chemical substances whose introduction into the body may likewise be followed by this process. Recent observers have maintained that there is a marked difference between a mere accumulation of leucocytes and an abscess proper. In the first instance there may be present a serous or fibrinous exudate entangled with a number of emigrated leucocytes, without a loss of tissue, without, therefore, suppuration. In the latter instance a certain amount of tissue is destroyed and directly transformed into pus. If this view be correct, it certainly strongly supports our present notions of the process of suppuration herewith laid before you in this résumé of my paper.

1. Inflammation is a disturbance of nutrition of a tissue causing a recurrence of the embryonal condition of the tissue involved.

2. The embryonal condition is established by the breaking up of the tissue into those medullary or indifferent corpuscles which, at an early stage of normal development, have built up the tissue.

3. The medullary corpuscles arise not only from the protoplasmic bodies of the tissue, the so-called "cells," but also the intercellular or basis substance is productive of such corpuscles,

as these have shared in the formation of basis substance in the process of normal development.

4. The medullary or indifferent corpuscles will still represent a tissue so long as they remain interconnected and continuous. By a simple reappearance of basis substance the most favorable termination is established, so-called "resolution."

5. If the inflammatory or medullary corpuscles have largely augmented, a number thereby remaining in original connection, the result will be productive, viz.: with a newly formed tissue of increased size, a so-called "hyperplasia."

6. If the inflammatory corpuscles springing from previous "cells," basis substance and blood-vessels break asunder and become isolated, they will be suspended in an albuminous liquid, they will henceforth represent pus corpuscles.

7. Pus, therefore, is a destroyed tissue broken up into its constituent elements, and as such unfit for production of a new tissue, although the single pus corpuscle will remain alive and amoeboid almost indefinitely as long as they are sufficiently nourished.

8. The emigration of colorless blood corpuscles certainly participates in the formation of pus and in the purulent discharge of proud flesh or granulation tissue, and is probably the main source of the pus.

9. Suppuration is caused by the presence of certain microbes, mainly the three varieties of staphylococcus, only when a previous inflammation be present in the tissue, furnishing a favorable soil for the development of the before mentioned microbes.

10. Staphylococcus is not the only antecedent of suppuration, it having been proved by experiments that the introduction of certain chemical agents, unfavorable to the development of microbes, may likewise be followed by suppuration.

## THE CLIMATE OF SOUTHERN ALBERTA AND ITS RELATION TO HEALTH AND DISEASE.

*Abstract of a Paper read at the Annual Meeting of the Canada Medical Association, Banff, Alberta, August 10, 1889.*

BY G. A. KENNEDY, M.D.,  
OF MACLEOD, CANADA

It appears to me that no apology is necessary in introducing the subject of this paper. It is only a few years since the opening of our great National highway brought the Northwest Territories into touch with the rest of the world; and only a few years further back since these vast plains and mountains, which are now so quickly becoming the homes of civilized man, were regarded as an inhospitable desert, fit only for the buffaloes which roamed their solitudes and the Indians subsisting on the chase. The past five years have been epoch-making so far as our great

West is concerned. Coincident with, and following on the building of the Canadian Pacific Railway, a flood of light began to illumine the Eastern intelligence, and as a consequence settlement has steadily and in a gradually increasing stream poured into the Territories.

It will be readily understood that a country almost equal in area to Russia must have many diversities of climate. As I cannot undertake to speak for the whole of the Northwest, I have limited my remarks to that part with which I am best acquainted, viz.: that strip of country lying along the eastern base of the mountains, and more particularly the southern part of this—bounded, say, on the north by the C. P. Ry. I make the eastern limit a line drawn north and south through Lethbridge, although for all practical purposes this line can be extended as far east as Medicine Hat. On the south is the International boundary line, and to the west the summit line of the Rockies and British Columbia. This Southern Alberta comprises an area of 150 miles square, of mountains, foothills and prairie. It is intersected every few miles by mountain streams as yet unpolluted by the filth and garbage of more thickly settled communities. Its general character is treeless save along the valleys of these streams, which are fringed by the willow and cottonwood, and on the sides and bases of the mountains. To the outside world this is known as Canada's grazing country, whence England will draw a large part of its future beef supply. As a sort of corollary to this, it has also been known in a general way that it was reputed to have a milder climate than the rest of the Northwest Territories. To most of you the following description will be not only interesting but necessary to a proper understanding of what follows. It is taken from an admirable paper by Mr. C. C. McCaul, of Lethbridge, published in the August number of the *American Meteorological Review*. After noticing that winter only really sets in about the middle of December, he goes on to say:

It is characterized by a maximum of bright, still, cloudless days, a scanty snow fall, and frequent and prolonged breaks of warm weather, heralded by the Chinook wind, of which more hereafter. Occasionally a bad snow storm will cover the prairie and hill to a depth of 18 or 20 inches. This, however, is very exceptional. The winter generally breaks up in February by a grand blow from the west, followed by a period of from one to three weeks of warm, bright weather, which may fairly be called the beginning of spring. Spring, here as elsewhere, is the most variable and capricious season of the year. On the whole it may, perhaps, be described as cold and damp, with frequent rainfalls, varied by bursts of the most gloriously bright warm weather, lasting sometimes a fortnight or three weeks.

May is generally fine, warm and bright: June

and the earlier part of July rainy; the remainder of July, August, September, October, and generally November, warm and very dry. The summer, July to September, is characterized by hot days and cool nights, with very little rain, but the warm, lazy days of autumn, often lasting well into December, are the glory of the year.

The grand characteristic of the climate as a whole, that on which the *weather* hinges, is the Chinook wind. It blows from west to southwest, in varying degrees of strength, from the gentle breeze that just tosses the heads of the daisies and sunflowers, to the howling gale that carries off contributions of chimneys, barrels, shingles, hats, and miscellaneous rubbish to our neighbors in Assinaboia. In winter, the wind is distinctly warm; in summer not so distinctly cool. Its approach is heralded by the massing of dark cumulus clouds about the mountain tops, and a distant wailing and rumbling from the passes and gorges. Its effect in winter is little short of miraculous. When a *real* Chinook blows, the thermometer often rises in a few hours from 20° below to 40° above zero; the snow, which in the morning may have been a foot deep, disappears before night; everything is dripping; but before another night falls all the water is lapped up by the thirsty wind, and the prairie is so dry that a horse's hoofs hardly make an impression upon it as you take your first welcome canter, after a prolonged and tedious spell of "settin' round the stove."

It may be added to this that the elevation above sea level of the plains here varies from 2,700 feet at Lethbridge to 4,500 feet at the entrance of the Crow's Nest Pass, which may be taken as the base of the mountains proper.

The winter and early spring are characterized by the coughs and colds incident to these seasons in almost any country. Summer is very healthy, and in autumn there are occasional cases of malarial fever of a remittent type, of which more hereafter.

Rheumatism is remarkably rare when one considers the sudden changes of temperature that often occur and the fact that most of the male population have led lives of the greatest exposure. When it *does* occur, it is almost always in the subacute or chronic form. Affections of the lungs are also very infrequent.

Summer disorders are almost unknown, a fact which must be attributed partly to the sparseness of population, but which is largely due, in my opinion, to the cool nights. About nervous affections I am hardly in a position to speak, but I judge that the rarefied air and the sometimes high winds would not be beneficial. During the past four years I have had three cases of paralysis—hemiplegia, occurring in patients otherwise perfectly healthy, cowboys in the prime and vigor of manhood, who have had no specific disease and were quite temperate, and whose family history

the most careful inquiry found irreproachable. These cases were and are a puzzle to me, and I can imagine no cause but excessive riding.

I have alluded to the existence of an endemic malarial fever occurring principally in the fall. This is general throughout the territories, and has given rise to much comment and some difference of opinion among medical men. Its character is variously modified by the season, climate, soil and immediate surroundings of the locality in which it is present. It has been called remittent, intermittent, malarial, typho-malarial, and typhoid according as a certain set of symptoms predominated, and is known throughout all the West by laymen as "mountain fever." I have seen this fever at its highest, characterized by a chill and symptoms of a heavy cold, and broken up at once by free diaphoresis and a dose of quinine. On the other hand, I have attended cases in which all treatment was of no avail, cases badly affected by environment, that would go on from bad to worse until they would sink into the typhoid state—too often only the beginning of the end. Between these extremes all grades of severity are met with—their most general characteristic being, however, their atypical character. Routine treatment is therefore impossible except, perhaps, at the beginning, when I make it a rule to relieve the bowels by a calomel purge, promote free diaphoresis by pulv. ipecac co. or antipyrin, sometimes a combination of the two, and give two or three large doses of quinine. Subsequent treatment on general principles.

I have alluded to the different names by which this fever has been called and the consequent confusion. The cause of this is the tendency to regard it as a distinct typical disease, *which it is not*. The cause may be the same (no one, I believe, has ever questioned its malarial nature); but the variations in the course, symptoms and severity are important enough to entitle them to be called almost distinct types. These variations are due to locality, to the season, to different conditions of soil, climate, atmospheric moisture, etc., and to the individual. Another cause of the confusion has been the occasional occurrence of typhoid fever and the incautious use of the unfortunate term "typho-malarial." I say unfortunate because I believe that from the time of its coinage in 1861–2, it has never ceased to be a cloak for uncertainty, an unknown quantity in statistics, and an added difficulty to the struggling and inexperienced practitioner. It would be a good thing, in my opinion, if it were expunged from the nomenclature of disease; for, notwithstanding the care that was exercised in its definition by the U. S. Commission, wherein it was distinctly pointed out that it was "not a specific or distinct type of disease, but a term conveniently applied to the compound forms of fever which result from the combined influences of the causes of the malari-

rious fevers and typhoid fever," *there has been* a tendency to elevate it into a distinct type of disease. In the Northwest, while I have often seen severe cases of malarial remittent falling into the typhoid state and cases of typhoid masked at first by malaria; while I confess I have been sometimes at a loss at first to classify my case, I can hardly recall an instance in which waiting a few days did not clear up the diagnosis.

In 1886 I made an attempt to have collected detailed reports of all cases of fever occurring throughout the Northwest, so that the special features of each district might become better known. This attempt was frustrated through ignorance or misapprehension of my motive. It is a matter of regret to me that my suggestions were not adopted, for I am not one of those who believe that we have reached the sum possible of attainable knowledge with regard to malaria. We owe much to the researches of Thomanasi, Crudele and Klebs, Laveran, Osler and Carter, in tracing out the life history in the blood of the malarial plasmodium. But I believe the future has still something to unfold to us of its nature, mode of action outside of, and entrance into the human system. And I believe we have yet much to learn of the relations between the paludal and typhoid poisons. I find it difficult to believe the story of the statistics which tells us that typhoid fever pure and simple is three, four and five times more fatal than the same fever complicated with malaria, and I believe that more care in the diagnosis, which is now rendered somewhat easier by the application of Ehrlich's test; more thoroughness in the recording of cases, and more attention to etiology, will help us to clear up these doubtful points which few will question are stumbling-blocks in our path.

I trust that I have not been misunderstood—that while remarking on this fever at greater length, perhaps, than its importance warrants, I have not led you to the belief that it is a constant menace to life, and health in Southern Alberta. I should be sorry to have made this impression, which would be an entirely false one. Some years the country is entirely free from fever; and generally it is mild and readily amenable to treatment. And severe cases will no doubt become rarer when greater care is exercised in personal and domestic sanitation.

I believe I have now said the worst that can be said of the climate of Southern Alberta, and I consider that in doing so I have earned the right to dwell briefly on what appears to me its distinguishing characteristic. I allude to its freedom from diseases of the lungs and its value as a resort or place of living for phthisical patients. I have already spoken of the rarity of pneumonia and other lung affections. I know of two cases of phthisis occurring in the country—one of acute tuberculosis strongly hereditary, and which proved

fatal, and another of fibroid, the cause of which I believe to be the fine dust of the corral acting in the same manner as stone mason's and knife grinder's disease. This latter steadily improved on ceasing work and is now almost well.

On the other hand, I have known of a great many cases of incipient phthisis that have come to Alberta, and in some the disease has been arrested and in others the sufferer restored to perfect health. These facts will not appear strange when the prevailing conditions are considered; for, according to the latest consensus of opinion among climatologists, the climatic treatment of phthisis requires:

1. A dry aseptic atmosphere.
2. A dry soil.
3. The greatest possible number of clear, sunshiny days during which the invalid can exercise in the open air.

4. A certain amount or degree of elevation above sea level. Equability of temperature within certain limits is not now considered necessary.

I believe I may assert without danger of contradiction that Southern Alberta possesses all these requisites in the most eminent degree. The dryness of the atmosphere is insured by the character of the country, a great grassy, undulating, treeless plain, elevated from 2,000 to 5,000 feet above sea level and distant several hundreds of miles from any considerable body of water. Accurate meteorological data are wanting, but it is sufficient to say that Alberta is not different from that whole strip of country lying at the eastern base of the continental watershed, and which the absence of a sufficient rainfall has caused to be devoted principally to the raising of stock. This dryness of the air, combined with its elevation, almost necessarily renders it aseptic in a wonderful degree.

Elevation is not now considered an essential feature in the climatic treatment of phthisis. The altitude theory, which Miguel did so much to bring into favor and which was so great an advance on the indiscriminate employment of places like Madeira and Havana—places where warmth and equability of temperature and a certain degree of moisture were prevailing features—is now slowly going out of fashion. But it is doubtful if even the immense power of fashion—which, it is to be deplored, is almost as great in medicine as in millinery—will ever be able to seriously affect in the medical mind the value of elevation. The reason it is not so much considered now is that it was found that the curative properties were the dryness and purity of the air, and not necessarily the elevation. But it is difficult, almost impossible, to find a dry aseptic atmosphere<sup>1</sup> without the elevation being near sea level, and for this reason, if for no other, patients in search of a climate will still throng to the elevated regions. Besides, the

<sup>1</sup> Excepting Aiken, Georgia.

other physiological effects of elevation; the increased respiratory activity and expansion of the lungs and chest walls, the consequent increased nutrition, the cool nights, almost compelling sound and refreshing sleep, are features of no little value in the altitude treatment. As before mentioned, the elevation in Southern Alberta varies from 2,000 to 5,000 feet, and the patient can therefore choose the locality which seems to suit best his particular case.

Laennec, Bowditch, Buchanan and others having made it very clear that soil moisture is one of the chief causes of phthisis, a dry soil must be considered a necessity for any place putting forth claims to be regarded as a resort or place of living for consumptives. While I am not able to give the geological formation of Southern Alberta, I can assert without fear of contradiction that its soil must be regarded as preëminently a dry one.

Perhaps a more important point than any of the foregoing—certainly a most necessary one—is the number of days during which patients can take exercise in the open air. Here the want of meteorological observations is again severely felt, but from a private record kept during the five years ending December, 1888, I am able to deduce the following: The number of days which are recorded as overcast, raining and snowing is respectively 51, 49, 56, 53, 44, being an average of a fraction over 50, all the rest being noted as fine. Over 50 per cent. of these (fifty) are simply overcast, so it is fairly presumable that in the large majority of them, confinement to the house would be unnecessary. These observations, moreover, were taken very close to the mountains, where local storms are more prevalent than on the plains.

As to the class of cases for which Southern Alberta is suitable I am content to take Dr. Knight's selection, which is, I believe, approved by the great balance of authority on the subject. It comprises:

1. Those presenting the earliest physical signs of tuberculosis of the apex, who have as yet shown little if any general disturbance from the disease, and who complain only of morning cough and expectoration. As Dr. Knight very truly remarks, the prognosis in this class has been changed from very bad to very good by the improved ideas of treatment.

2. Hæmorrhagic cases without marked febrile reaction or much physical evidence of disease.

3. Certain cases of "fibroid" or "interstitial" pneumonia.

4. Patients recovering from acute pleurisy or pneumonia in whom the irruption of tubercle is dreaded.

For these classes of cases, Southern Alberta offers inducements hardly excelled by any place on the continent. I trust I have already satisfied you that the necessary climatic conditions are present: the dry aseptic atmosphere, the dry soil,

the clear sunshiny days and the necessary elevation. There are one or two other points which I feel compelled to mention. One is that seekers after health are not obliged to remain for a few months only, and then go away again on the approach of winter or summer. Another is that, being a stock-raising country, it is easily possible to spend almost all one's time in the saddle. It was Sydenham who said that "unlimited horseback exercise is almost as good a cure for phthisis as quinine for ague." Another is that Alberta is in Canada, for why should Canadian physicians send their patients to Colorado when they have a climate equally as good within the confines of their own Dominion?

The general conditions of life are those of any new and growing country. Many of the pleasures of the East have to be dispensed with, but to most people, the bright sunny skies, the pure, bracing, intoxicating air, the exhilarating freedom of outdoor life and the unrivaled scenery of Alberta, will amply compensate for the artificial pleasures they are obliged to forego.

## MEDICAL PROGRESS.

**JABORANDI AS A PARTURIFACIENT.**—Under this caption Dr. N. P. Moss reports a few cases (*N. O. Med. and Surg. Journ.*) in which jaborandi seemed to expedite labor, and his explanation of the *modus operandi* of the drug is unsatisfactory, as he seems to attribute it merely to its diaphoretic properties. His cases are also not numerous enough to serve as a basis for accurate deductions. Pilocarpin has been proven beyond doubt to possess a powerful action upon the uterus, and it has been employed to a considerable extent as an abortifacient. Professor Schauta, of Prague, has employed pilocarpin in more than forty cases as a means of strengthening labor pains. Injected subcutaneously he has found it active in 2 per cent. solution, although he has also used it in 3 or 4 per cent. solutions. Schauta went so far as to measure the effects of his doses by means of the manometer, and reached the conclusion that the influence of pilocarpin upon the uterus is a very powerful one, although it varies greatly according to individual susceptibility. In 1881 Van der Mey made experiments upon pregnant rabbits from which he obtained similar results. Gigollet has reported the case of a woman in whom premature labor was twice induced by the administration of pilocarpin, three injections at intervals of four hours having proved sufficient. Prof. Schauta gives the following rules for the administration of pilocarpin: After careful examination of the organs of respiration and circulation I would administer on the first day, if necessary,

as many as three injections of a 2 per cent. solution. If by the second day no contractions had supervened, I would use not more than two injections of a 3 per cent. solution; and finally, on the third day one or two injections of a 4 per cent. solution, employing always the muriate of pilocarpin. If I obtained no action by the fifth day I would resort to other measures. It would be absurd to abandon the use of muriate of pilocarpin, which has proved itself such an excellent ebolic remedy in some cases, simply because it has not been found active in all cases when used in a 2 per cent. solution.

**ABDOMINAL ANEURISM.**—DR. WM. F. DREWRY, of Petersburg, Va., reports the following case: The patient, a negro æt. 60 years, was admitted into the Central Lunatic Asylum of Virginia on March 15, 1889. An aneurism of the upper third of the abdominal aorta was easily diagnosed. Iodide of potassium, acetate of lead, anodyne embrocations, etc., were prescribed. On May 17 the patient died while asleep. An autopsy revealed the following conditions: In the upper half of the abdominal aorta, in the vicinity of and involving the orifice of the coeliac axis, and arising from the anterior face of the aorta, a false sacculated aneurism was found, with a mean diameter of 6 inches. It was intimately adherent to the adjacent tissues and encroached somewhat upon the spinal column. The sac had ruptured, perforating the diaphragm, and the contents had escaped into the left pleura. The reporter refers to the following statistics: Of 551 cases of aneurism of the aorta tabulated by Crips, only 59 were abdominal. Of 880 cases collected by Sibson only 177 occurred in the abdominal portion, and of this number 131 were located at or near the coeliac axis. Of 103 cases of abdominal aneurism collected by Lebert only 3 occurred at or near the bifurcation. Biggs, of New York, has recently reported 33 cases of aneurism of the aorta, only 4 of which were in the abdominal pylorus. Regarding the termination of abdominal aneurisms Sibson says: Seventy-seven per cent. rupture—28.5 per cent. into the peritoneal cavity; 22 per cent. into the subperitoneal tissue in the left hypochondriac region. — *Virginia Medical Monthly*, July, 1889.

**PEPTONURIA IN PREGNANCY.** By DR. WILLIAM FISCHEL.—In my work on puerperal peptonuria, I reported casually the occurrence of peptone in the urine of pregnant women. I wish to add that the pregnant women referred to were kept under observation up to the time of their confinement and even beyond, and that they remained healthy and especially were free from skin eruptions and syphilides. They all bore healthy living children. Inasmuch as I found peptone in one-fourth of the urine examined, I cannot at all agree with Dr. Koettwitz (*Deut. Med. Woch.*, 1888, p. 613), who, as the result of his observations, re-

ported that the peptonuria of pregnancy is followed by death and maceration of the fœtus. Peptonuria certainly does occur in cases where the fœtus does not die. I cannot say whether Koettwitz's negative results of examination depend upon the reaction adopted by him, or whether it was a matter of chance that he always found the urine free from peptone. The positive results which I obtained by careful analyses according to approved methods, in Prof. Huppert's laboratory, cannot be set aside, whether they appear plausible or not.

I also wish to direct attention to the fact that the conditions explained by Dr. Koettwitz, under which alone he conceives the peptonuria of pregnancy possible, would be explained by me in the same manner. But it must be remembered that the pains of pregnancy do not occur merely at the end of gestation, as Dr. Koettwitz says, but during the entire period thereof, and accordingly, on the basis of this hypothesis, peptonuria may occur at any time during pregnancy. That this hypothesis is not proven, appears from my former reports; as does also the fact that it is not the only conceivable one.—*Centralbl. für Gyn.*

**A CASE OF FŒTUS PAPYRACEUS.**—DR. E. W. MULLIGAN, of Rochester, N. Y., reports a case of this kind. He first saw his patient in November, 1888, when she was apparently having labor pains. She considered herself to be in the sixth month of pregnancy, although the large size of the abdomen seemed to indicate a more advanced pregnancy. Patient was not seen again for three months, when she was found in labor; the abdomen, curiously enough, was much smaller than it was three months before. Patient soon gave birth to a child weighing 10 lbs. which was immediately followed by the expulsion of a dead fœtus. This was flattened out and seemed to correspond to the sixth month of fetal development. The cord was slightly attached to the border of the placenta. The woman now said that soon after the physician's previous visit the membranes broke and almost a *paillful* of clear fluid escaped, after which the pains subsided and she went about her duties as usual.

*Double Vagina and Uterus.*—Dr. Mulligan also reports for Dr. Jonas Jones the case of a well developed woman 25 years old, married two years without children. External genitals normal. There are two vaginæ situated side by side, the opening of the left one being a little above and to the right in relation to the other. They appear to be about the same size, but the right one, having been used, received the speculum more readily. Each uterus is 2½ inches in depth, the os being normal in each. The patient has had two miscarriages in the past three years, miscarrying each time when two months pregnant.—*Buffalo Med. and Surg. Journal*, August, 1889.

SATURDAY, SEPTEMBER 14, 1889.

GRAILEY HEWITT<sup>1</sup> ON THE SEVERE VOMITING  
OF PREGNANCY.

DR. GRAILEY HEWITT'S most recent communication "On the Severe Vomiting of Pregnancy," read at the last meeting of the American Gynecological Society, merited critical attention and adequate discussion. But it is a somewhat remarkable fact that neither the presence of the distinguished author himself, nor the valuable nature of his essay, was sufficient to draw out lively debate. The explanation, however, of this apparent slight put upon a foreigner is not hard to find. The surgical aspects of obstetrics and the diseases of women received the attention that ought to have been devoted to equally weighty matters of internal medicine.

Dr. Hewitt's paper relates chiefly to etiology—undoubtedly the topic of greatest import. He writes: "The conclusion suggested is, substantially in agreement with the opinion of Desormeaux, expressed some years ago, that the vomiting is due to interference with expansion of the uterus. The cases related in this paper appear to show that there are two factors which principally contribute to this interference with uterine expansion: 1. Incarceration of the uterus in the pelvis associated with flexion or version; and 2. Undue hardness and rigidity of the tissues of the cervix and around the os internum. Also that these two factors are in most cases associated."

Those familiar with the earlier utterances of Dr. Hewitt will recognize a material change of

opinion in this most recent expression. Flexions and versions, in general, and anteversions in particular, no longer exercise dominant power in determining hyperemesis. But this amended hypothesis is no more equal to the explanation of all recorded cases of the uncontrollable vomiting of pregnancy, than were its less pretentious antecedents.

In the limited space at our command, it is impossible to enter into a detailed criticism of Dr. Hewitt's analysis and elaborate classification of recorded cases. In passing, however, it may be remarked that in the construction of his premises, he has assumed the question at issue, while he treats with a certain insular arrogance the opinions of other observers. Indeed, his treatment of the entire subject can hardly be regarded as candid.

In a number of cases, quoted in his paper, and in a still larger number of examples described in the literature of the subject, the vomiting and prostration either appeared for the first time, or became marked, after the uterus had passed upward out of the pelvis into the abdominal cavity. In other words, the symptoms presented themselves at a time when the operation of the factors mentioned by Dr. Hewitt must have been physically impossible.

There are scarcely six cases of incarceration of the ante-flexed pregnant uterus on record. Then the symptoms of incarceration of the pregnant uterus, whether it be bent or turned forward or backward, or fixed by exudates and the like, make up a clinical picture essentially different from that we see in the uncontrollable vomiting of pregnancy. Incarceration causes pronounced local disorders, in connection with the function, of the bladder and rectum, that are more or less acute. These disturbances commonly attract the patient's attention to her own condition. When vomiting occurs it is usually the vomiting of ileus, not of pregnancy. The clinical characters of the vomiting from incarceration of the pregnant uterus are not identical with the appearances of hyperemesis gravidarum. The former is a subordinate phenomenon, appears late, and lasts necessarily but a brief period. The latter rules the situation from the first, constitutes the complete clinical picture of the disease, and runs a chronic course.

Dr. Hewitt does not mention a considerable

<sup>1</sup> Transactions of the American Gynecological Society, Vol. xiii, 1885. British Medical Journal, 1889

class of cases, in which the determining cause of the vomiting is found in some morbid state of the gastric mucous membrane, often existent before conception. It is well-known that pregnancy not only often exaggerates physiological processes into morbid activity, but also that it seriously aggravates conditions of little moment in the non-gravid woman. The adjuvant cause of hyperemesis gravidarum is not uncommonly discovered in latent chronic gastritis, or in acute gastritis arising during pregnancy. Gastric ulcer is of more common occurrence and attended with greater significance in pregnant women than is generally believed.

The causation of the uncontrollable vomiting of pregnancy constitutes a most intricate problem, and while etiological research has cleared up some obscurities, there still remain cases in which the autopsy fails to disclose any adequate objective changes. Under such circumstances is it not better to admit ignorance, rather than to force a favorite hypothesis?

#### MEDICAL ORGANIZATION.

At a recent session of the California State Medical Society, a resolution was adopted declaring that continuous membership in a local society, where one exists, is essential for membership in the State society. In pursuance of this action, the Sacramento Society, regarding this as an important step in the maintenance of the local organization, adopted similar action.

We are glad to note this as a real advance in the proper direction. In a number of States, the State society only exists as the parent head of the county or other local societies. This we believe to be the only proper means to secure the organization of the profession and to control those who are inclined to irregularities. In the early days of medical societies, especially in the new States, it was not always possible to wait on the local bodies prior to the formation of the State body. In fact, in some instances it was necessary to combine the members of the profession in a State medical society at the outset, and by means of organizing committees to cause the local societies to radiate from it as a centre.

But medical organizations have now become so well known and their workings so well understood that this plan is no longer needed. Every county

should have its own society, or where the members of the profession are extremely few in number, let them join with one or more adjoining counties and form a district society, which should annually send its delegates to the State society and to the American Medical Association. By the amendment to the laws of this latter body, providing for "Members by Application," every regular physician has an opportunity to become a full member of the general body. This should be embraced by all and the admission of "Members by Invitation" should be of rare occurrence. This latter privilege should only be accorded to distinguished strangers, and never to those who are able to join by application, or who do not feel sufficient interest in their local society to aid it by their money and influence.

Although the next session of the American Medical Association will not take place until May of 1890, yet it is none too early for the profession of the South and West, in whose midst that session is to be held, to take steps toward the thorough organization of every portion. The session at Nashville should be one of the grandest gatherings ever assembled. As the securing of rates on the railroads will on that occasion be solely confided to the hands of one person, and as he is the one to whom application is usually made by those who desire to obtain these reductions, we feel confident that on this occasion it will, if possible, be secured in abundance of time for all to avail themselves of the reduction.

The organization of a medical society need not be a difficult task. In districts not yet provided for, let the physicians assemble at the call of one of their number. There is always a central figure around whom the rest will cluster; let him issue a call and see to it that no worthy member is omitted. In medicine there is no creed or politics. Every physician should be admitted to the local society against whom there is no charge of irregular conduct. Let the assemblage adopt the simplest laws for its government, place the fees of whatever kind as low as will be sufficient to provide for the maintenance of the society, select the best members for officers, particularly for president and secretary, for upon these two officers the whole usefulness of the body will depend. This done, let the society apply to the State Medical Society for recognition by representation, as upon such recognition de-

pends its right to send delegates to the American Medical Association. Such an organization will continue as an integral part of the medical fraternity with but little effort on the part of its members.

To make the sessions useful and attractive, it would be well to have a committee on essays, whose duty will be to provide for each meeting some literary entertainment in the form of an essay, clinical report, or similar matter, and the hour of meeting will soon come to be regarded as a pleasure and its coming anticipated by all.

In many such meetings we have known them to be looked forward to as an opportunity to renew friendly greetings, to make new acquaintances, as well as to learn what was new in the profession.

In a very large experience of this kind, we have known the warmest friendships to have been formed, mutual misunderstandings explained, a feeling of sociability to be established, which has done much to cause the entire profession of the locality to gain the respect of the community. In conclusion, let us urge these points upon the profession everywhere; organize, and where societies already exist, make them stronger, bring in every one who is eligible; thus you will elevate the profession at home, in your State, and in the whole country.

#### EDITORIAL NOTES.

##### HOME.

**TYPHOID FEVER IN INDIANA.**—Typhoid fever prevails at Dundee and Connorsville. It is of a malignant type and is spreading rapidly.

**A PECULIAR CATTLE DISEASE.**—Cattle are dying in the vicinity of Dallas City, Hancock county, Ill., of a strange disease. They become stiff in the hindquarters and suddenly drop to the ground, dying in great agony.

**THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE,** which concluded its sessions in Toronto last week, decided to hold its next meeting at Indianapolis in August, 1890.

**WOMAN'S MEDICAL COLLEGE OF CHICAGO.**—The Woman's Medical College celebrated the opening of its twentieth year of instruction on the 3d inst. at the College building on South

Lincoln street. Dr. William H. Byford, President, and Professor Mary Mixer made brief addresses. Already over one hundred students have been enrolled for the present year, a very large increase over the former attendance.

**THE AMERICAN SOCIETY OF MICROSCOPISTS** held their twelfth annual meeting at Buffalo during the third week in August. There was a large attendance of members and the following officers were elected: President, George E. Fell, M.D., Buffalo; Vice-Presidents, W. H. Seaman, Washington, D. C., and F. W. Kuhne, Fort Wayne, Ind.; Treasurer (to fill the unexpired term of Dr. Mosgrove, resigned), C. C. Mellor, Pittsburgh, Pa.; Executive Committee, W. P. Manton, Detroit, Mich.; Dr. Frank L. James, St. Louis; W. H. Walmsley, Philadelphia, Pa. The time and place of next meeting is not yet announced.

**THE ASSOCIATION OF AMERICAN PHYSICIANS,** as previously announced, will hold their Fourth Annual Meeting at Washington on the 18th, 19th and 20th insts., under the presidency of Dr. Francis Minot, of Boston. Papers will be read on the following subjects: "The Early Stage of General Paralysis," by Dr. C. F. Folsom, of Boston; "Tetany," by Dr. James Stewart, of Montreal; "Tetany and a New Theory of its Pathology," by Dr. John T. Carpenter, of Pottsville; "Thrombosis of the Cerebral Sinuses and Veins," by Dr. A. B. Ball, of New York; "Chylous Effusions into Serous Cavities," by Dr. S. C. Busey, of Washington; "Substitutes for Opium in Chronic Diseases," by Dr. J. F. A. Adams, of Pittsfield; "Remarkable Case of Slow Pulse," by Dr. D. W. Prentiss, of Washington; Discussion on the Relation between Chlorosis, Simple Anæmia, and Pernicious Anæmia, including Lencocythæmia and Hodgkins' Disease, Referee, Dr. Frederick P. Henry, of Philadelphia, Co-Referee, Dr. F. Forchheimer, of Cincinnati; "Primary Cancer of the Duodenum," by Dr. E. N. Whittier, of Boston; "Primary Cancer of the Gall Bladder and Ducts," by Dr. John H. Musser, of Philadelphia; "Gastric Neurasthenia," by Dr. G. M. Garland, of Boston; "Specimens from Two Cases of Cretinism," by Dr. W. F. Whitney, of Boston; "The Anatomical and Physiological Relations of Lesions of the Heart and Kidneys," by Dr. H. F. Formad, of Philadelphia; "The Contagium of Diphtheria," by Dr. P. Gervais

Robinson, of St. Louis; "A Supplementary Inquiry into the Frequency with which Lead is Found in the Urine," by Dr. James J. Putnam, of Boston; Discussion on the Relations of Rheumatism to Rheumatoid Arthritis. Referee, Dr. William Osler, of Baltimore, Co-Referee, Dr. Morris Longstreth, of Philadelphia; "How Far may a Cow be Tuberculous before the Milk Becomes Dangerous as a Food Supply?" by Dr. Harold C. Ernst, of Jamaica Plain; "The Bacillus Tuberculosis," by Dr. J. T. Whittaker, of Cincinnati; "Hot Air Inhalations in Tubercloses," by Dr. E. L. Trudeau, of Saranac Lake.

MORE EXPERIENCE WITH THE "ELIXIR OF LIFE."—Samuel C. Showalter, of Dayton, Ohio, aged 60, voluntarily submitted to injection of elixir of life three weeks ago, hoping for relief from rheumatism, and died on the 2d inst. from the effects of the treatment. Immediately after the injection was made his limbs began to swell and his whole system was permeated with blood poison.

THE DEATH-RATE IN CALIFORNIA.—The deaths registered in 81 town districts of California, with a population of 790,700, corresponded, for the month of July, to an annual rate of 13.33 per mil. The average annual death-rate from all causes occurring in the ten largest cities and towns, with a population of 620,000, was 12.57 per mil.

METEOROLOGICAL REPORTS from San Diego and San Francisco for June, 1889, furnish the following data: Mean temp., San Diego, 64°; San Francisco, 58.1°. Highest temp., San Diego, 72°; San Francisco, 75°. Lowest temp., San Diego, 56°; San Francisco, 52°. Mean daily range of temp., San Diego, 10.5°; San Francisco, 12.1°. Total rainfall, San Diego, 0.10; San Francisco, 0.03.

THE USE OF MORPHINE IN DELIRIUM TREMENS.—Another one of those cases (unfortunately by no means rare) where a patient suffering from delirium tremens dies after the administration of moderate doses of morphine is reported in the *Occidental Medical Times*. In this instance, as often happens, the press dispatches reported that death occurred from an overdose of morphine administered by the physician. The autopsy showed no evidence of morphine poisoning, but

did reveal a clot in the left lateral ventricle. In view of the fact that such reports are often recorded and that opium is an unsafe remedy in cases of threatened apoplexy, the physician certainly acts the part of prudence when he withholds the use of morphine in delirium tremens and trusts to more reliable sedatives.

LORETA'S OPERATION FOR STRICTURE OF THE PYLORUS.—Dr. T. W. Huntington, of California, reports a case where he performed Loreta's operation for stricture of the pylorus in a patient who had suffered from gastric derangement for three years. After dilation of the constricted portion the former symptoms disappeared, and five weeks after the operation the patient had resumed his usual diet and is pronounced practically well.

METAL REMOVED FROM THE EYEBALL BY AN ELECTRO-MAGNET.—Dr. W. E. Briggs, of Sacramento, reports, in the *Occidental Medical Times*, nine cases of operation for removal of metal from the eyeball by means of the electro-magnet. There were two successful cases of removal from the anterior chamber, three of removal from the vitreous, and one of removal from the ciliary regions. In two cases of failure, enucleation of the eyeball followed, and in one case of failure the patient refused enucleation and passed from observation. Dr. Briggs summarizes his conclusions as follows: The electro-magnet is generally a safer instrument for the extraction of fragments of steel from the anterior chamber, from the iris, or from the anterior portion of the lens, than the forceps. It is practically our only resource when the steel has penetrated the vitreous chamber. It is safe to retain, quite extensively, injured eyes, if the offending body be promptly removed and thorough asepsis observed.

AN ARMY MEDICAL BOARD will be convened in New York City, New York, October 1, 1889, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the Army. Application for invitation should be addressed to the Secretary of War, stating date and place of birth; place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character, and moral habits; testimonials as to professional standing, from the professors of the medical col-

lege from which the applicant graduated, are also desirable. The candidate must be between 21 and 28 years of age, and a graduate from a regular medical college, evidence of which, his diploma, must be submitted to the Board. Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

#### FOREIGN.

**TO INSPECT DRAINAGE SYSTEMS.**—Ellis Clark, President of the Association of Municipal and Sanitary Engineers of England, will sail on the *Servia* on the 21st inst. for the purpose of acquainting himself with the methods adopted in large cities in the United States for the disposal of sewage and refuse, and also with internal sanitary arrangements.

**COLLECTIVE INVESTIGATION.**—It is to be regretted that the Collective Investigation Committee of the British Medical Association, from whom so much was expected, feels obliged to recommend the abandonment of the work of collective investigation. The Committee reports that the returns received upon the subjects which have been taken up have been so few that they do not feel justified in continuing the inquiries further or in entering upon fresh ones.

**THE TERCENTENNIAL OF THE MICROSCOPE.**—Preparations are being made in several German towns to celebrate next year the three hundredth anniversary of the invention of the microscope. Zacharias Janssen, of Madgeburg, is credited with having constructed the first microscope in 1590.

**DR. LUSTGARTEN.**—It is announced that Dr. Lustgarten, of Vienna, is about to remove permanently to this country. Dr. Lustgarten will be remembered especially by reason of his discovery in 1885 of the bacillus of syphilis. At the time his report was received with a great deal of incredulity, but it was not long in obtaining the recognition of the highest authorities. As Assistant to Prof. Kaposi (the successor of Hebra) Dr. Lustgarten became personally known to many of the American physicians who have visited Vienna within the last few years.

**PROFS. BREISKY AND ULTMANN.**—The Vienna Medical Faculty has recently suffered severe losses in the death of Prof. Breisky, the distin-

guished obstetrician, and that of the no less eminent professor of urinary diseases, Prof. Ultmann, both of whom were well known in this country for their valuable contributions to medical literature. Prof. Ultmann, from his longer residence in Vienna, was particularly well known to us, and numbered his American pupils by the score. Those who were so fortunate as to have attended his admirable clinics at the Policlinic will long retain pleasant recollections of his skill as well as his kindly demeanor toward his patients.

**AN INQUIRY INTO THE MANAGEMENT OF MEDICAL CHARITIES.**—The following resolution will be moved at the next session of the British Medical Association: "That this meeting of the British Medical Association views with great pleasure the action of the Charity Organization Society of London in presenting a petition to the House of Lords praying for an inquiry into the management of the metropolitan medical charities, and earnestly hopes that the scope of the inquiry will be extended so as to include provincial hospitals and dispensaries, with the view of obtaining as complete information as is possible upon this important subject; that a copy of this resolution be forwarded to the Lord President of the Privy Council, and that he be requested to receive a deputation; that the Council be requested to appoint a special committee to deal with the question, and request the Charity Organization Society of England to form a similar committee to act in conjunction with it."

**IN GREAT BRITAIN** a new wing is about to be added to the Leeds Infirmary. Dr. Thomas King Chambers, honorary physician to the Prince of Wales and a member of the General Medical Council, is dead. An epidemic of typhus fever has been prevalent in the Marshalltown division of the Mitchelstown district, Ireland. Londoners have been alarmed over an alleged outbreak of typhoid fever in the West end. The Glasgow Town Council have been considering the necessity of making new arrangements for meat inspection, and have decided to place the inspection of meat in charge of the sanitary department, and have appointed a committee to consider what further legislation is necessary to secure the public against the sale of tuberculous and infected meat. At the recent quarterly meeting of the Royal College of Surgeons of England Mr. Jonathan Hutchinson was elected President, and Messrs. Bryant and Croft Vice-Presidents.

## TOPICS OF THE WEEK.

## THE HYGIENIC USES OF THE IMAGINATION.

In a recent editorial entitled "CONSIDERATE JUDGMENT," we endeavored to emphasize the necessity of basing conclusions upon well ascertained facts, and stated that only those theories which could be thus substantiated would be found enduring. But in the attainment of truth we are by no means debarred the full and free play of a well disciplined imagination; indeed, it often points the way to undiscovered truths; it is by no means infallible; its suggestions always need verification; but imaginations verified become with us accepted facts. Under the above heading, at the recent meeting of the British Medical Association, SIR JAMES CRICHTON BROWNE presented a very able address which is reported in the *British Medical Journal* of August 24, and from which we make the following abstract:

The cultivation of the imagination, then—and it can be cultivated and disciplined to agility and steadiness of action—is of high importance to us as medical men; for it can be serviceable to us in collecting materials, in solving difficult problems, and, by the analogies it suggests, in guiding us in our life-long search after truth. The precise character which medicine is happily assuming, as its several departments merge into the exact sciences, and which demands of its cultivators a physico-mathematical and chemical training of ever increasing stringency, does not in any degree abrogate the necessity for the employment of the imagination. On the physical side of medicine that still holds its own, and on its psychical side it is indispensable in dealing with phenomena that are beyond the province of physical and chemical research. Medical men and medical students, then, need not fear that they are altogether wasting their time when they turn aside now and then from their professional tasks to ramble for a little in the green pastures of literature, or climb the pinnacles of art. True, their imagination may be fully trained for its professional duty, as it is exercised, in conjunction with observation and judgment, in the scientific sphere; but it will be braced, invigorated, and have its resources multiplied, by recreating occasionally in its native air. Even if imaginative pursuits did not strengthen the hands of medical men in grappling with disease, or quicken their scientific vision, these would still be commendable, because of the refreshment they bring to jaded brains. To turn from the fatigue and anxieties of practice into realms where rivalry is no more and night bells never ring is to plunge into one of the most soothing and depurative of "tired Nature's" baths. Members of our profession are, I suspect, generally aware of this, and resort to imaginative literature, music, and art more than any other class of professional men, except, of course, artists and men of letters, and to an extent that is remarkable, considering the engrossing claims made on their time and the scant leisure they enjoy.

The contributions of medical men to the departments of imaginative work have been far from insignificant. At least four eminent members of our profession now living might be named who have found leisure, amidst

absorbing occupation, so to use the pencil and brush as to gratify not only their private circles but the public, and a list of medical poets would be a long and goodly one, including such names as Akenside (the gifted singer of the pleasures of that imagination whose usefulness I am attempting to extol), Garth, Blackmore, Goldsmith, Smollet, Armstrong, Erasmus Darwin, Crabbe, Moir (better known as Delta, John Brown, whose *Rab and His Friends* is idyllic, and Oliver Wendell Holmes. Nay, even one or two of the greatest names in poetical literature might not improperly be added to such a list. Keats was apprenticed to a surgeon at Edmonton, and afterwards attended St. Thomas' Hospital. It has been argued, I am afraid not very convincingly, that Shakespeare's extensive medical knowledge proves him to have been engaged in the study of medicine during one or two of those years of his life that are unaccounted for, but it is indisputable that Dante was enrolled amongst the *medici e speziali* (leeches and druggists) of Florence, and that he attended their council meetings for several years. But it is not as producers but as consumers of poetry and imaginative literature that medical men derive from them their restorative influence; and as consumers they are, I feel sure, amongst the bookseller's best friends. Sydenham, when asked by Sir Richard Blackmore what course of study he would recommend for a medical student, replied, "Let him read *Don Quixote*, it is a very good book; I read it still." Connolly, the apostle of that non-restraint system to which we owe everything that is most excellent in the treatment of the insane in this country, and with which I trust professional opinion and public sentiment will permit no tampering—Connolly told me in his latter years that he took ever renewed delight in *Gulliver's Travels*. I know hard-working doctors in town and country who hold habitual converse with some of our great imaginative writers. Two of the most distinguished and busiest physicians of this day are, to my knowledge, inveterate novel readers. I have heard one of our great surgeons deliver an address betraying a deep study of the poetry of Keats; and another of our great surgeons, present at this meeting, told me recently that on his way to and from every serious operation he dips into Shelley.

But it may be objected that the imagination, if sometimes stimulating and restorative in its influence, is often morbid in its tendencies, and that its indulgence is to be guarded against by those who desire to possess well regulated minds. "No habit can be more opposed to a healthy condition of the mental powers," says Abercrombie, "than that which permits the mind to wander in a mere vision or waking dream from scene to scene, unrestrained by reason, probability or truth;" and the answer to Abercrombie is supplied by Tyndall, who says that those who have denounced the imagination because they have seen its disastrous effect on weak vessels, "might with equal justice point to exploded boilers as an argument against the use of steam." But the weak vessels wrecked by imagination are really fewer than is commonly supposed. Now and again some erratic genius, of highly strung nervous temperament, gives himself up to the pleasures of imagination till he becomes intox-

icated with them, and staggers over the boundary of sanity. Now and again an intensely imaginative child, like Jerome Cardan or Hartley Coleridge, so indulges in day dreams that his fancies grow into phantoms that haunt him; but I do not hesitate to say that for one case of insanity caused by excess of imagination, there are a dozen caused by the want of it. Apathetic dullness and torpor of mind are apt to deepen into dementia; and those entirely given up to "the care of this life and the deceitfulness of riches" are more likely to be choked by them than those who can surmount them, and breathe the free and ample air of æsthetical emotion. A vulgar error as to the nature of insanity has perhaps conduced to exaggeration as to the dangers of imagination. Visitors to asylums invariably arrive expecting to find growths of morbid invention and belief, wild, tangled, and luxuriant as a tropical forest, and leave much disappointed by the barrenness of the land, for the insane are the least imaginative of beings. At rare intervals a madman is encountered—a Blake or a Swedenborg—whom two intrepid doctors have certified, who dazzles all around him by the meteoric brilliancy of his conceptions; but, as a rule, the lunatic is as dull as a stone. He is the victim of a fixed idea, or his delusions pursue a treadmill round, or occur in groups so unvarying that, if you have ascertained one of them, you can predict all the rest. His mind is a blank or a blurred and unreadable page, or his fancies, if they come thick in the tumult of mania, are so disjointed or huddled together as to defy recognition. Idiocy is the absolute negation of imagination, and insanity undermines and destroys or enfeebles it more or less, and, when we try to drive out insanity, the first thing we do is to invoke imagination's aid, for moral treatment consists mainly in appeals to this faculty, and fully acknowledges its hygienic uses. The first recorded cure of melancholia was by the harp of David, and to-day in every lunatic hospital worth the name persistent efforts are being made by music, by pictures, by poetry and the drama to stimulate the imagination, and thus "cleanse the stuffed bosom of that perilous stuff that weighs upon the heart."

Imagination seems to have a trophic influence on the brain. When it is absent tardy growth goes on; when it is more or less in abeyance, weakness exists; when it is active, there is vigorous development; and the immediate effects of imagination in causing exhilaration and preventing sleep when it is excessively indulged almost suggest that the states of the cortex which accompany it have some control over metabolic changes in the body. We now know that, besides alkaloids exercising a poisonous effect, which owe their formation to microbes, and are called ptomaines, there are others which are produced by the cells of the living organism themselves in breaking down albuminous matter, and which are called leucomaines. Now Bonchard has shown that the alkaloids of the latter kind formed during sleep have a stimulating action, so that, when they accumulate to a certain amount, they excite the nerve centres and cause awakening, while those formed during waking hours have a depressing action and tend to induce sleep. And it is just possible that in the formation of leucomaines of different

classes, under varying conditions of the supreme nerve centres, a key may be found to the curious fact that certain emotional moods, after having persisted for a time, tend to induce their opposites—excitement, depression; appetite, disgust—and also to the influence of imagination, when very active, in causing exhilaration and wakefulness. It is just possible that under such circumstances it may arrest the formation of those leucomaines, usually manufactured during waking hours, which are depressing and lead up to sleep, or so modify decomposition that other leucomaines of a stimulating character are produced. There can be no question that, in insanity, certain states of the highest nerve centres are accompanied by rapid disintegration of the tissues and emaciation, while in other states of these centres metabolism is reduced to a minimum, so that prolonged starvation may be sustained with comparatively little wasting.

But it is only an inordinate indulgence of the imagination that produces excitement and interferes with natural slumber; its reasonable and regulated use causing only a certain buoyancy of spirits with which a sense of soothing is associated. Imagination, indeed, legitimately used, combines to some extent the pleasurable effects of both morphine and caffeine, without any disagreeable after-consequences, such as headaches, despondency, or confusion of thought. On the one hand, it may heighten happiness, and on the other afford solace in suffering and sorrow. It may give zest to appetite and allay the pangs of hunger, brace to exertion, or lessen the sense of fatigue. It would not be wrong to speak of it, when rightly used, as a true physiological stimulant, and analgesic, capable in some degree of taking the place of those crude agents drawn from herbs and trees, with which in all quarters of the globe mankind has sought to mitigate the dullness or assuage the pains of life. Moreover, its massive pleasures have a distinctly sedative effect in connection with those petty but exasperating animosities and jealousies that are the thorns of social intercourse, and fret and fray fine-textured brains. Lifting us above the turmoils and worries of the moment and opening up wide and distant prospects, they promote altruistic feeling, lull to rest our wounded sensibilities, and allay feverish excitement.

#### SENILE CHANGES IN ARTERIES.

In discussing the nature of constitutional susceptibility to disease in his recent address at Leeds, DR. JOSEPH COATS, of Glasgow, makes reference to senile changes in arteries in the following language:

Turning to susceptibilities to disease, I believe that senile changes constitute a very important element in the commoner diseases of arteries. Atheroma of arteries and aneurysms, arising as these do for the most part from atheroma, are conditions in which we can distinctly trace the two elements in the cansation which I alluded to at the outset of this address. These are diseases of middle life and old age, that is to say, senile changes in the arteries constitute the predisposing cause or susceptibility, but the determining cause is the impact of the blood on the wall of the artery. This is evident from the fact that atheroma is commonest where that impact is greatest,

namely in the aorta. It is not common in arteries of comparatively small calibre, but there are two situations in which it frequently occurs even in small vessels, and these are situations where the impact of the blood is apt to be greater than in other arteries of a similar size. The coronary arteries of the heart, coming off directly from the aorta, are exposed to a high blood-pressure, and they are very often atheromatous. The arteries of the brain also, coming off as the anterior and middle cerebral do from a large artery which passes up directly from the aorta, are presumably exposed to unusual blood-pressure, and they are very frequently affected with atheroma. Perhaps also the soft character of the brain substance, causing the arteries to be less supported than most others, may have to do with the frequency of atheroma here. In this disease, then, the changes of constitution in the arteries consequent on many years of activity induce a condition which renders the tissues of these vessels incapable of resisting, as before, the effects of the blood-pressure. This change of constitution we may infer to be a diminished vitality in the living structures forming the walls of the vessels. That it is so is almost demonstrated by the fact that atheroma is often associated with a condition of the middle coat, which implies greatly diminished vitality, namely, calcification of the muscle cells of that coat. Before a living structure allows of the deposition of lime salts in it, it is already so much reduced in vitality as to be almost dead.

Now it is interesting to observe that these senile changes in the constitution of arteries are subject to very great variations in different individuals, and in like manner the occurrence of atheroma varies, both in the age at which it occurs and in its extent. This is of great importance when we consider what an important part this disease plays in causing death in old people. A large proportion of the deaths in the latter part of middle life and in old age are from hæmorrhage or softening of the brain, presenting itself in the various forms of apoplexy, paralysis and brain weakness. These conditions of the brain mostly depend on atheroma of the arteries, and so we may say that the tendency to death is greatly influenced by the occurrence or the premature occurrence of the senile changes which render the arteries susceptible to atheroma. The constitutional condition of the arteries as regards vitality of their tissues in advanced life exercises thus a very important influence on the duration of life. I may venture to say that the constitutional powers of the heart and of the arteries are the principal factors in determining longevity. The ability of the heart varies greatly in different individuals, and survival when attacked by an acute disease will largely depend on the power of the heart to resist the debilitating influence of the morbid agent. If a man passes through middle life and has escaped from acute diseases, or has survived them, then the condition of his arteries is probably the most important factor in determining his chances of life. It is thus that the local constitutional peculiarities of the vascular system influence the duration of life. These constitutional conditions, like others, are largely the subject of inheritance, which thus again is seen to determine local peculiarities.

#### KIND TREATMENT FOR THE CURE OF DEMENTIA.

During the past week the American Social Science Association has been in session at Saratoga. A good common sense paper on "Training Insane Women in Domestic Industry" was read by General Secretary Sanborn, who prefaced his remarks by saying that in the general interest now aroused by industrial education he had thought the success of Miss Alice R. Cooke, of Sandwich, Mass., author of the above paper, in restoring to industrious habits insane persons who had become idle through loss of mental power and the lack of mental direction, would be of value, and this paper was the result. Miss Cooke said she took three women from asylums where they had been five years or more, all of Irish extraction, the youngest being about 30 years of age, and the oldest about 60. All were suffering from dementia, characterized by melancholia and delusions. Her treatment was simply kindness with thoughtful care, and her success in restoring them to constant usefulness in household service was made the basis of an argument showing the desirability of placing the chronic and quiet insane in private families rather than in the noise and confusion of public hospitals, where their disease is aggravated by the quarrels and violent outbreaks of different classes of patients. She thought what she had accomplished with these middle-aged women could be done still more effectively with the younger ones and those of more vigorous bodily health. This was followed by a general discussion relative to the training of defective classes in labor.

## SOCIETY PROCEEDINGS.

### Medical Society of the District of Columbia.

*Stated Meeting, February 20, 1889.*

CHARLES E. HAGNER, M.D., PRESIDENT,  
IN THE CHAIR.

DR. I. BERMANN read a paper on

#### THE POSSIBILITY OF LATENT SYPHILIS CAUSING INFECTION.

*(Discussion Concluded from page 355.)*

DR. SMITH: All men and women who contract syphilis will lie about it. Unless Dr. Bermann could swear that this man did not contract the disease since his marriage and that this woman did not cohabit with anybody else, he could not help doubting infection from such a long latency. He then gave the history of a case where the woman told several stories and protested her innocence, and several years after she admitted that she had been indiscreet a number of times with several men. If Dr. Bermann could get the true history of his case he might find that there had been a little lying going on.

DR. THOMPSON: The question of infection through the semen is a very interesting one

Most syphilographers agree that infection must be through the foetus. Could this man, at this length of time since primary infection, infect his wife? He thought not. There were secondary manifestations, and not tertiary, after eleven years latency, according to Dr. Bermann's diagnosis. He questioned the correctness of the diagnosis. He had not proved syphilis. The man could not infect his wife from glandular enlargements. The diagnosis was false. He did not believe this man had syphilis. He had seen a young man to-day who had an eruption resembling the secondary manifestations of syphilis, with glandular enlargements; but there was no evidence of local lesions, and he declared that he had never had intercourse with a woman. Five years ago he had treated a man for the mildest form of syphilis; he afterward traveled and returned to perfect health. He came to him a few days ago with a suppurating gland, similar to a venereal bubo, and still he declares that he has not been exposed. According to the theory advanced to-night this man could infect his wife and children. Dr. Thompson did not believe that this young man could give his wife syphilis by copulation, or could infect his children through his wife.

DR. BERMANN: The cases cited by Dr. Thompson and his own are not at all alike, and, therefore, not comparable. Dr. Bermann was certain of his diagnosis. He could make as good a diagnosis as any one, and when he did diagnosticate syphilis he was as competent to do so as any one in this country or anywhere else. He had seen enough cases of syphilis to be sure of it when he made his diagnosis; and when he said a man had syphilis he felt sure it could be relied upon.

DR. THOMPSON: The cases were similar. Both had syphilis and were said to be well, but years afterwards developed symptoms resembling the secondary manifestations of syphilis. He was surprised at the wild statement of Dr. Bermann as to his powers of diagnosticating a disease surrounded by as many uncertainties as syphilis. He was surprised to hear a gentleman get up in a body of intelligent men and utter such an opinion. Dr. Thompson had visited the clinics of men with large experience in syphilitic diseases, and never heard one of them make such a rash statement. They are constantly changing their opinion. He had seen many cases in which they could not tell with certainty what the disease was due to, but suspected syphilis; but suspicions are not facts, and are not reliable in correct diagnosticating. If Dr. Bermann had not obtained the history in his cases he did not believe that he would have attempted to diagnosticate syphilis from such meagre manifestations. He had not proved that either of these patients had syphilis by one positive sign; until he did, then the diagnosis would be questionable. We all see ulcerations that resemble syphilitic ulcerations, but we

would not make a diagnosis from these alone at such a remote period after primary infection.

DR. BUSEY was seeking information. It had been definitely stated by Dr. Thompson that syphilis would not remain latent for so many years. The question is, did either of these patients have syphilis? The point seems to be settled that if the man had syphilis it did not remain latent so long, and if the woman had it the infection was more recent than claimed by Dr. Bermann. Assuming that the latency was not as long as it was said to be, the diagnosis is not positive. He did not believe the woman could have contracted the disease through the pregnancy and not have manifestations for so long a time. He coincided with the view expressed by Dr. Thompson, that if the woman had syphilis she contracted it long after the time stated in the report.

DR. BERMANN was very glad to hear Drs. Thompson and Busey testify to the absolute necessity of making an exact diagnosis, and felt very much relieved, consequently, as that absolved him from having been too arrogant in taking a firm stand regarding the exactness of a diagnosis he had made in a case fully as important as that of extra-uterine pregnancy, and much easier to make. A fair and scientific criticism of the subject brought before this Society for discussion can only be welcome to all members; but such objections as those made by disputing without giving any reasons, the correct diagnosis of a case they have never seen, and which had been under his observation for a long time, he could not consider either fair or scientific.

Zeiss says: Repeated observations, however, have taught us that persons affected with latent, feeble syphilis, though having no syphilitic effects on any part of their bodies, may communicate the disease to their wives, although it is not possible to discover any initial syphilitic lesion in the latter, and have not become pregnant. In these women syphilis manifests itself by extremely rapid emaciation. In the further course of the disease they lose their hair; sometimes periosteal swellings come on in some of the bones, and subsequently the menses become profuse and recur frequently. On becoming pregnant they will often abort. In what manner the syphilitic contagion in such cases has gained an entrance into the system is not yet clearly known. We know just as little in what manner a woman who suffers from latent syphilis is capable of communicating the disease to her husband. Possibly in such cases the blood has served to transmit the infection, some bleeding erosions or excoriations having occurred on the genital organs.

Neumann, to whom Dr. Thompson refers, says: Though it is not possible to draw the line absolutely between secondary and tertiary symptoms, still experience teaches that some forms of syphilis show soon after infection, that means in more

acute fashion, while others appear only several years after infection. The tertiary symptoms begin not before seven or eight months have elapsed. Not infrequently it can be observed that the so-called tertiary symptoms develop after the lapse of several years, without any secondary symptoms having been observed.

In regard to Dr. Thompson's statement about the use of mercury and iodine in such cases, a well known author states :

"Mercury as a rub is advantageous in proportion to the nearness of the symptoms for which it is given to the primary lesion, while iodine is nearly a specific for the later manifestations. The intermediary symptoms require both medicines combined.

"Syphilis may manifest itself as a mild eruption after chancre, disappearing possibly without treatment, and then, exceptionally it is true, lie latent for many years, as long as 52 years, to reappear with characters due only to syphilitic disease."

Bumstead and Taylor say: "It has been proved that the semen is not an infecting fluid, as are syphilitic blood and the excretions of specific lesions; moreover, every physician with experience has met with many instances of syphilitic men cohabiting for years with healthy women who never show any evidence of syphilis.

"The physiological secretions of syphilitic persons, the milk, saliva, urine, perspiration and tears, most probably are not vehicles of syphilitic poison. They may probably contain it, but in such an exceedingly dilute state as to be innocuous. However, one of the physiological secretions, the semen, seems to form an exception to this rule.

"Whether the semen of a man affected with latent syphilis may be the medium of contagion to the wife remains yet an open question. Von Barrensprung claims that this can be so only when the wife conceives. Others, as Porter and Langston Parker, have reported cases which tend to show that infection of the wife may take place without conception, solely through the direct action of the semen, and at the same time without the production on her part of any discoverable primary lesion. The difficulty experienced in ascertaining the real facts in such cases is materially increased from the fact that the primary lesion upon the internal genitals of the female is often very superficial, and lasts but a short time. H. Lee is of the opinion, however, that in these cases the semen does not cause the infection itself, but only through the admixture with it of syphilitic virus from the urethral mucous membrane.

"On the other hand, the virulence of the semen of a syphilitic father for a child he begets is an unquestionable fact."

The point that Dr. Smith made that people

with syphilis will lie even to their physicians is unquestionably true, but in his case the man's word could be relied on, as he had every reason to know and there was no reason for him to conceal any facts after he had acknowledged to having been treated for syphilis. The wife, when she came to him, had tertiary manifestations, as is sufficiently proved by the specific effects which iodide of potassium had in her case. If she had contracted the disease illegitimately, she would have been more likely to have come under observation long before it had come to the manifestation of tertiary symptoms. Furthermore, experience teaches, as Fournier in his works on Syphilis and Marriage shows, that the rule is that the wife is infected by the husband, and his authority, he thought, would not be questioned.

DR. THOMPSON said his one idea in all discussions was to consider matters brought before this society simply from a scientific standpoint, in order that a thorough, satisfactory, and at the same time impersonal discussion might be possible. He believed that the other members of the society would agree with him in saying that the extracts read by Dr. Bermann were admirably adapted to support the views expressed by him, and rather weakened than strengthened those of Dr. Bermann. He thought that no competent authority of the present believed that a woman could acquire syphilis by the semen unless through the foetus after impregnation. Fournier has inoculated with the semen of syphilitics without effect. The point which he would emphasize was that rather than believe that the patient had acquired syphilis from the semen of a syphilitic he would doubt Dr. Bermann's diagnosis. It is true that if an individual had a specific sore in the mouth the saliva which came in contact with it might infect another, and so could the semen passing over a sore in the urethra; but saliva and semen as such did not and could not infect. Further, while secondary syphilitic lesions were inoculable, tertiary were not.

In regard to the diagnosis of the primary lesion, if Dr. Bermann meant that some syphilitic sores were so characteristic that no one could possibly make a mistake, he agreed with him; but the true Hunterian chancre does not represent one-half the infecting sores. Sometimes these are so slight that the patient would not discover their existence, and this has repeatedly occurred, even in the person of physicians. Many slight erosions or abrasions may occur which are not the least characteristic, and which readily disappear upon simple treatment. But, nevertheless, it is possible for even these to infect with syphilis, or a person may become infected through them. There are no hard and fast lines to be drawn between the appearances of the chancre and chancroid—the infecting and non-infecting sore. Characteristic examples of each are met with, but again other

sores occur which it is impossible to refer definitely to either category simply from their naked-eye appearances. The woman in Dr. Bermann's case was exposed constantly throughout her married life to infection from her husband, but who could tell when it occurred? If syphilis were present inoculation must have occurred in this way; for supposing that even the sore in the man's month was a gumma, infection from it was not possible. Dr. Bermann had said that it was possible to differentiate in ulcers of the throat between specific and non-specific. This was always difficult. At the present time he had under observation, in an elderly maiden lady—where the existence of syphilis was out of the question—a leg ulcer which had all the appearances of being specific, but which was healing rapidly under the simplest general and local treatment.

DR. BUSEY expressed his surprise that Dr. Bermann should have believed that he had made an attack upon him.

DR. BERMAN had referred to Baumler's opinions in regard to the subject in hand which on being rehearsed seemed to support the stand taken by Dr. Thompson.

DR. BUSEY asked if Dr. Bermann now said that he did not know when the woman was infected with syphilis why he had presented the case as one of latent syphilis of long standing?

DR. BERMAN reiterated his belief that his case was one of infection by latent syphilis.

*Stated Meeting, February 27, 1889.*

DR. HAGNER IN THE CHAIR.

DR. D. S. LAMB presented

SPECIMEN OF TUBERCULAR PERITONITIS.

Uterus and appendages and left lung. Peritoneum covering uterus and appendages was everywhere studded with small flat tubercles about 2 lines in diameter. The lung was compressed so that there was no air in it. Specimens from a colored woman who had had fever, night-sweats, brown tongue, cough, brownish expectoration, emaciation; diarrhoea and constipation alternated; tympanites; severe abdominal pain, especially in epigastric, umbilical and right iliac regions. The post-mortem examination showed the peritoneum everywhere as in the specimen; the parenchyma of the organs, the mucous membrane of the intestines, and the lymphatics of the abdomen not affected. Right lung oedematous; left lung as described; was compressed by a large serous effusion in pleura; pleura of lung thickened. Abdominal organs adherent everywhere; some adhesions slight; others, especially in the right iliac region, old and firm. Liver small and fatty; spleen small. Kidneys normal. Brain and heart normal.

Also, a specimen of extra-uterine pregnancy.

The mother, a colored woman, age 27, had been married one year when she began to show signs of pregnancy in October, 1888. After a time she had colicky pains, and towards January, 1889, had, at short intervals, some hæmorrhage per vaginam; a tumor also appeared in right ilio-lumbar region. In January the hæmorrhages were more profuse and frequent. She died suddenly February 20th. The post-mortem examination showed the right Fallopian tube converted into a large sac, with placental wall ruptured at one end, where a four-months' foetus had escaped; left tube much distended with watery fluid; small corpus luteum in *left* ovary; some old adhesions around right tube and to omentum. Lungs normal; slight thickening on one aortic segment. Abdominal organs normal, except as mentioned. Abdomen full of blood-clots and serum.

DR. BUSEY was extremely interested in these cases, and in the extra-uterine pregnancy he was desirous to obtain a correct record of knowing if he had understood Dr. Lamb to say that the patient had had symptoms in the second, third, and again in the fourth month.

DR. LAMB remarked that there had been pain in each of the three months, and the discharge spoken of had occurred one month before death.

DR. BUSEY thought that the patient had not been examined carefully, and that in all probability operative interference at the right time might have saved her life. Referring to the case reported sometime since to the Washington Obstetrical and Gynecological Society, by Dr. Smith, he observed that the case had only been seen after death by Dr. Smith, but the symptoms seemed by him to have been sufficiently pronounced to have excited the suspicion of her attending physician. Here then were two specimens, presented within a short time of each other, removed post-mortem from patients who had died of a ruptured extra-fœtation sac, and in both cases it was fair to suppose that if the diagnosis had been made, and abdominal section performed, a fatal termination might have been averted.

DR. SMITH asked Dr. Busey if he had ever seen a case of ectopic pregnancy. He reviewed the history of the case alluded to by Dr. Busey, which had previously been reported by him. The patient was pregnant three months, but there had been no symptom pointing distinctly to the existence of an extra-uterine fœtation before those presented themselves which immediately preceded and accompanied the fatal issue. Four days before her death the patient sent for Dr. Smith, and she then complained of intense abdominal pain, most marked in the epigastric region. The temperature and pulse were normal but there was some vomiting. The next day the symptoms were the same, but were somewhat mitigated by the treat-

ment pursued. On the evening of the fourth day he saw her again and left her comfortable. There was no pain or tenderness in or over the abdomen, nor any symptoms of hæmorrhage or shock. At his next visit he found the woman dead. Throughout the whole history of the case there was nothing to indicate the existence of an anomalous pregnancy. The only thing which produced disturbance was some frequency and painfulness in micturition. At midnight, a few hours after Dr. Smith's visit, she awoke her sister—who was sleeping with her—and told her she was dying. She was anxious to have her feet elevated. Dr. Holden, who lives in the neighborhood, was hastily summoned, and reached her about half-past one. He gave her stimulants hypodermatically, but without avail, as she soon died.

Dr. Smith, continuing, said that Dr. Busey was of the opinion that the diagnosis should have been made in this case, and in that reported by Dr. Lamb, but the inherent difficulties of the diagnosis in this condition should not be forgotten. At a recent society meeting in Philadelphia Dr. Parvin had said that, after all, the diagnosis in such cases of ectopic pregnancy was a happy guess. Many others, whose names are familiar to us as active and intelligent gynecologists, had participated in this discussion, but the general consensus of opinion was that the whole question of diagnosis was beset with the utmost difficulties. Indeed, even after operation, it is not always easy to decide that an ectopic pregnancy really existed; and in one case, to which attention was called, in New York, the specimen had first to be submitted to a microscopist before this decision could be arrived at.

So far as the history of ectopic pregnancy in this city was concerned, there were eight or ten specimens in the Army Medical Museum, all of which had been removed after death.

In any woman where the menses have ceased and the uterus on examination proves to be enlarged, the inference is that normal pregnancy exists. In his own case the uterus was of the size to correspond with the existing term of uterogestation. This being ascertained, there having been nothing to point to the existence of anything abnormal, the examination was concluded.

The symptoms of ectopic pregnancy are really those of pregnancy plus abortion; and if an examination is made and no abortion is found to be taking place then the suspicion of extra-uterine pregnancy is at once excited. Suppose, under these conditions, a tumor is found at the side or behind the uterus, are we justified in performing abdominal section and removing it? Dr. Smith thought that we were, and would go farther and say that anything less than such a procedure was an injustice to the patient. It would be more excusable to fail to make a diagnosis than having made it fail to remove the abnormally-seated product of conception.

DR. BUSEY remarked that, having trusted to his memory when first speaking of Dr. Smith's case, he had made an error in believing that Dr. Smith did not see his patient until the time immediately preceding or coincident with the fatal termination. It now transpires that he saw her four days before this and, without desiring to cast any blame upon Dr. Smith, he thought most assuredly the diagnosis should have been made. Even although he could not have made the diagnosis completely and accurately he should have discovered the tumor. He differs again with Dr. Smith as to the unvarying employment of laparotomy even if the diagnosis is assured, for even as great an authority as Thomas conceives laparotomy to be the last, not the first resort. He believed that laparotomy may be but is not invariably best. Yet, in either of these cases laparotomy would not only have been justified, but was imperative, when symptoms of impending dissolution appeared. At the time of rupture abdominal section was imperative, but not always before this.

DR. SMITH asked Dr. Busey if not laparotomy, then what other method of treatment was indicated before rupture?

DR. BUSEY: Electricity is the alternative.

DR. J. FORD THOMPSON referred to the importance of the subject under discussion and urged its exhaustive study and thorough elaboration. His own opinions were not in perfect consonance with those of Dr. Smith or those of Dr. Busey. He thought that in the vast majority of cases of ectopic pregnancy the diagnosis ought to be made. When the surgeon is called upon to decide the nature of an abdominal or pelvic tumor coexisting with pregnancy, and in connection with the symptoms which have already been alluded to, he must confess that there is little ground for confusion. He was anxious that not too much weight be placed upon the opinion of accepted authorities, for upon these matters any one of surgical experience is entitled to entertain and express his individual opinion.

He was in accord with Dr. Busey as to the limits he puts upon abdominal section. Tait has reported forty-two cases of abdominal section for ruptured ectopic fetal sacs with but two deaths; and if such a result can be achieved at such a time, and under such unfavorable conditions of shock, etc., why not earlier? If early laparotomy is not performed the surgeon may never have the opportunity of operating at the time of rupture, for death may ensue before he reaches her bedside. It is the bounden duty of the surgeon to first make his diagnosis and then perform laparotomy. He regarded the sound as a valuable aid in diagnosis, although its use was deprecated by some. He considered electricity, or any other means of killing the fœtus, as inferior to laparotomy. Such a procedure does not save the woman; even though it averts immediate danger many accidents may sub-

sequently ensue, such as breaking down of the sac, and all the evils attending and following this process.

Laparotomy is best performed early, for then the operation is easy, no adhesions or other complications existing. He expressed himself as opposed to any method of killing the foetus provided it was allowed to remain within the abdominal cavity.

DR. G. W. JOHNSTON observed that it gave him great pleasure to listen to the preceding discussion of the subject of ectopic pregnancy, and he was glad that a matter so important was called so forcibly to the attention of the Society as had been done by the presentation of the specimen from one fatal case, and the narration of the history of another. Tait's views as to the nature and mode of origin of ectopic pregnancy were well known and needed no comment; and Dr. Lamb's specimen, in which there was tubal gestation on one side and grave disease on the other, would aid in the support of Tait's opinion as to the etiology of the condition. Dr. Johnston hoped that the tube which was diseased would be submitted to careful microscopic examination in order to ascertain the character of its lining mucous membrane, particularly with reference to the absence or presence of cilia upon its epithelial investment.

So far as the difficulty of the diagnosis before rupture was concerned, he believed that this was universally acknowledged, and while we all agreed that a diagnosis should be made it was not always easy to make it. The classical symptoms of this condition at this time were quite distinctive, but from a study of those cases where the diagnosis previously attempted or made had been confirmed by abdominal section during life or autopsy, he was convinced that many of the distinctive symptoms might be wanting although, in a certain proportion, so characteristic was the picture presented that it was hardly possible to see how one could have gone astray. While it appears, therefore, that in some cases of extra-uterine foetation, before rupture, many significant features of the affection may be absent, so that we are, as Tait puts it, rather confused than enlightened by the history of the case; on the other hand it is equally worthy of remark that certain other affections of the pelvic contents may be accompanied by symptoms, both subjective and objective, so like those which are said to accompany extra-uterine foetation that it is with surprise, on opening the abdomen, that the operator finds that it is not with an ectopic pregnancy, but with something entirely different, that he has to do.

In spite of the manifest difficulties which surround this subject we will all agree that nothing exceeds or, perhaps, even equals it in importance. It is a subject which is of the most vital importance, not only to the specialist, but the general

practitioner, and its importance has been immeasurably enhanced by the wonderful record of Tait's operations at the time of rupture, which are set forth in his work on "Ectopic Pregnancy," recently published.

America has just cause to be proud, however, not only for the work which her physicians have done in the development of electricity in the treatment of this condition, but more especially because two of its members have proven conclusively, by three cases, that the diagnosis could be made and the sac and its contents be successfully removed before rupture had taken place. To Dr. Joseph Price, of Philadelphia, who reported the first case, and to Dr. J. S. Hawley, of New York, who operated upon the others, too much credit cannot be given for this solution of a very difficult problem.

It would appear from the remarks just made in discussion that the use of electricity was attended by no danger. That this was not the invariable rule Dr. Janvrin's case (heretofore reported) proved very conclusively.

DR. SMITH desired to make some further remarks in regard to his own case. The day before his patient had been seized with the illness which proved to be her last, she had been actively engaged in washing clothes and hanging them on the line. She had, at the conclusion of this work, gone out to a neighboring store to make some needful purchases, and on her return attempted to castigate one of her children, a large boy. It is likely, therefore, that the rupture of the sac was immediately the consequence of her own indiscretion. He had previously treated this patient for retroversion of the uterus, and when he had first been called after her sudden attack he supposed that the gravid uterus, which he previously replaced, had again become dislocated. Examination showed the uterus to be occupying its normal position, and he presumed that it had fallen backward, but had subsequently spontaneously assumed its normal position.

Beside this there was a fibroid in the uterus, and the discovery of this body in the womb of a woman with signs of pregnancy served still further to complicate the diagnosis. He was thoroughly in accord with Greig Smith, who regarded laparotomy as imperative as soon as the diagnosis was made. He was opposed to the use of electricity, as after the foetus had been killed the woman was by no means free from danger. He referred to a case in which Dr. Mann, of Buffalo, had supposed that he had killed an ectopic foetus by electricity, while Dr. Kelly, of Philadelphia, who subsequently operated upon the patient, proved the supposed ectopic gestation sac to be an ovarian tumor. He quoted Dr. Formad, of Philadelphia, as saying that the majority of cases of extra-uterine pregnancy were diagnosed by the coroner. He referred also, in speaking of

the use of electricity, to the opinion of Reeve, expressed in the words: "One should never employ electricity in this condition unless his laparotomy instruments were at hand."

DR. FORD THOMPSON observed, in speaking of the usefulness of the sound for purposes of diagnosis, that when all other means of diagnosis had been exhausted, and the symptoms pointed to the existence of ectopic pregnancy, the introduction of the sound was perfectly justifiable, and in Dr. Smith's case this procedure might have led to the making of a correct diagnosis, and the saving of the patient's life.

DR. BUSEY asked if Dr. A. W. Johnstone, of Kentucky, had not been the first to remove an ectopic foetation sac before rupture?

DR. G. W. JOHNSTON replied that Dr. Joseph Price was the first to put such a case on record. The history of his case was very brief, and perhaps might be called incomplete. The second and third operations had been performed, as had been said, by Dr. Hawley, of New York, and the description given left nothing to be desired. Dr. Price's case appeared in the *Annals of Gynecology* and Dr. Hawley's in the *N. Y. Medical Journal*.

DR. BUSEY was convinced that in every case of ectopic pregnancy the diagnosis should be made. Heretofore, in speaking of ectopic pregnancy, he had had in mind only the tubal variety. To make his views upon treatment clear he would say that: 1. When rupture has occurred laparotomy is the sole and imperative operation; and 2. When an assured diagnosis has been arrived at previous to rupture, laparotomy is again the operation of election; but in that large group of cases where the existence of ectopic pregnancy is probable, but where an accurate diagnosis is impossible, electricity is preferable to laparotomy. While it is true that bad results have attended and followed its application in some instances, this was by no means most frequently the case; and the vast majority of instances nothing untoward had occurred, and success had followed its application.

DR. LAMB said that in his case a *corpus luteum* was noticed in the left ovary, while the pregnancy was in the right tube. He asked if any explanation could be offered for this state of things?

DR. G. W. JOHNSTON remarked that the introduction of a sound into the uterus for diagnostic purposes was by no means devoid of risk; the contraction of the uterus, and of the foetal sac, might thereby be induced, and fatal rupture was known to have occurred. In reply to a question of Dr. Thompson's, he said that he was not prepared to state definitely where he had seen such an assertion, but would endeavor to give him the desired information.

DR. S. S. ADAMS reported a case of FRACTURE OF SKULL AND LACERATION OF BRAIN.

B. F. C., white, N.Y., consulted me in August,

1887, for epilepsy, inherited from father. Full habit and addicted to use of alcoholic liquors. A seizure preceding night. Two or three slight paroxysms since. Feb. 22, 1889, was thrown from a carriage and sustained a number of contusions. Was confined to house till Feb. 26th, then returned to work in land office; at noon, while ascending inside stairs on north front, he fell backward. Was attended by Drs. Darby and Littleford. Dr. J. Ford Thompson called at once, and sewed scalp wound on right frontal eminence. I met Dr. T. at 5 P.M., when he made an exploratory incision on the right temporal region. Fracture detected, but no depression. Prognosis: Death would take place in a few hours, as it was believed that the brain had been lacerated. Active convulsions from time of accident till 7 P.M., after that profound coma until death, at midnight, 26th.

Necropsy, by Dr. D. S. Lamb, twelve hours after death, limited to the head: There was a large swelling in the right temporal region, due to hæmorrhage into and under the scalp. In this swollen part an angular incision had been made above and in front of the line of the ear. On the right side of the forehead was a lacerated wound of the skin corresponding to the frontal eminence, beneath which the bone was normal.

The right parietal bone was fissured longitudinally, the fissure crossed the coronal suture at the right temporal ridge and took an angular course to the left for a short distance over the frontal bone; posteriorly the fissure approached the occipital apex within 2 inches, and bifurcated into two branches, one extending downwards to the occipito-parietal suture, the other to the left, across the median line and a short distance beyond.

The brain was covered with dark blood-clots everywhere; there was a longitudinal laceration involving the lower part of the frontal and parietal lobes, and communicating with the surface in line of the lower end of the fissure of Rolando. The fractured bone showed many extravasations in the diploe.

## FOREIGN CORRESPONDENCE.

### LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

*London Hospitals and their Management—The Metropolitan Water Companies' Filter Beds—Spiro-ne in the Treatment of Consumption—The use of Poison for Criminal Purposes in India—The Death-rate of London—Miscellaneous Topics.*

The Government has pledged itself to take into consideration the whole question of the London hospitals and their management. Lord Sandhurst

in a speech showed that ample room exists for searching inquiry. It is undoubtedly the case that the multiplication of "special" hospitals during recent years has seriously diminished the incomes of the older institutions. This is a grave matter in itself, but it becomes graver still if it be true that the "special" hospitals are prone to extravagance. Sir Andrew Clarke's fancy sketch of the "Hospital for the Treatment of the Diseases of the Great Toe" has a good deal of truth at the back of its irony. It is not easy to see what the Government can do to stop this state of things, but even the knowledge that it hopes to do something may produce a beneficial effect for a time.

Major General Scott, the official water examiner, in his forthcoming report gives a favorable account of the condition and working of the Metropolitan Water Companies' filter beds. A normal limit to the rapidity of filtration has now been adopted, being at the rate of  $2\frac{1}{2}$  gallons through each square foot of the filtering surface, which consists of layers of sand and fine and coarse gravel. The local companies' filtration during last year appears to have been well within this limit. Sand is the efficient medium. Turbid water, however, after floods is difficult to deal with. The solid impurities in suspension chiefly consisting of clay, marl, and chalk in very finely divided state, can be got rid of only by long subsidence previous to filtration. Turbid water must of necessity be sometimes admitted, and filters are then overtaxed. Great stress is laid in the report upon the necessity of having cisterns properly covered so as to exclude both light and dirt, and they should be so placed that the water may be kept cool in summer without being in danger of freezing in the winter.

Spirone is the name given to a fluid which is claimed to be of great use in the treatment of consumption and a variety of pulmonary affections. It is also stated to be very efficacious in coryza. The quantity used is  $\frac{1}{2}$  oz. during the twenty-four hours, and this is best taken by inhaling about one-fourth of the total quantity for the twenty-four hours, as soon as the patient awakes or immediately after getting up. Another fourth should be taken before going to bed, and the remaining half should be used at intervals in dribbets during the day, especially if at any time there be a feeling of dryness, itching or tingling. The spray should be applied by blowing it somewhat vigorously against the back of the throat, making the jet strike successively the different parts of that region, the patient drawing it into the lungs at the same time. Two whiffs in succession should be given up each nostril, the head being thrown well back, and kept in that position, so that the spirone can trickle down the back of the throat. The first whiff is often very painful, especially for the first few days; the second is less so—the sensitiveness diminishing rapidly as the condition

of the mucous membrane improves. If two inhalations up each nostril are sufficient to produce entire relief they had better not be repeated during the day. If, however, at any time the nostrils, back of the nose or throat again appear irritated or uncomfortable, the application may be repeated. It is found, however, well not to use it for the nostrils more than four times altogether during the twenty-four hours, and the spray must not be delivered too forcibly, as in hay fever the mucous membrane of the nostril may easily be made to bleed, owing to its state of irritability and congestion. In hay fever the treatment should begin a few days before the expected attack. Even if the remission of the symptoms is complete, the treatment must not be left off, or even decreased for a week or ten days after the expiration of the period during which the disease generally lasts.

Some interesting reports are to hand relative to the employment of poison in India for criminal and other purposes during the year 1888. It would seem that the total number of such cases dealt with in the Government of Bombay for the twelve months was 360, while there were only 282 the preceding year. This enormous increase is accounted for partly from the fact that the use of poison for criminal purposes is becoming increasingly frequent each year. Vegetable poisons, which were most extensively used a few years ago, have been rapidly giving place to metallic poisons. This is ascribed by Dr. Lyon, the analyst to the Government, to the ease with which drugs such as arsenic are procurable at the present time, there being practically no restriction on their sale. Out of eighty-four undeniable cases of human poisoning, arsenic was employed in forty-one, copper in six, mercury in five, powdered glass in three, and red lead in three, while of the remaining twenty-seven cases opium appears to have been used in fifteen, datura in five, alcohol in two, prussic acid in one, and oleander and other plants in four. According to Dr. Lyon poisoning by means of powdered glass is, comparatively speaking, quite a recent innovation, and hence the number of cases which had come under his notice was smaller, probably, than it otherwise would have been. The return points irresistibly to the conclusion that deaths from criminal administration of metallic poison are not only common, but are in fact of increasing frequency in India at the present day.

Among the large towns of the United Kingdom, London during the past month, with a death-rate of 18.6, holds an honorable place in the latest returns of the public health. It is far behind Huddersfield, which reports only 10.7, and Derby, 12.2; but these are both very exceptional returns. Next in order comes Brighton, 14.6, and Bristol, 16.4. Absolutely the most unhealthy large town is Preston, with a death-rate

of 48.6. In the metropolis the most serious zymotic disease at present is diphtheria, from which there were forty-four deaths. Scarlet fever is prevalent, but the epidemic is of a mild form.

Dr. Norman Kerr, who was first drawn to the study of inebriety as a disease while working as a temperance reformer, points out that certain periods of life are accompanied by a special craving for stimulants, which disappears along with the physiological circumstances that caused the disturbance of the system. The habit of drunkenness, he asserts, may also result from some accident—may, indeed, be a symptom of some obscure brain disease.

Aix-les-Bains is grateful to British medical men for their appreciation of its mineral waters, and the municipality has recently determined to honor the profession in the person of a distinguished London physician, by giving to a new avenue the name of Sir Alfred Garrod.

In view of the excessive prevalence of infant mortality a select committee has recommended that the Friendly Societies Act should be so altered that the age for the insurance of juveniles be extended from 10 to 16 years, but that the total amount of insurance be absolutely limited, and for the security of infantile life suggests that the Registrar-General should add to the form of medical certificate of death a column demanding particulars of insurance on the life of deceased, to be filled up by the doctor in attendance on the family.

## MISCELLANY.

AMERICAN ACADEMY OF MEDICINE.—The Annual Meeting of the Academy, for 1889, will be held at Chicago, Ill., November 13th and 14th, being postponed to that date by authority of the Council.

RICHARD J. DUNGLISON, Secretary.  
Philadelphia, Sept. 1, 1889.

## LETTERS RECEIVED.

Dr. S. O. Bowen, Eastford, Conn.; B. Westermann & Co. New York; Dr. Jno. G. Ames, Marblehead, Mass.; Dr. W. H. Ashley, Shelburne Falls, Mass.; Dr. J. A. Hinton, Friendship, Tenn.; Shelby Morgan, Shelby, Ind.; Dr. John S. Marshall, Green Spring, O.; Dr. Samuel A. Fisk, Denver, Col.; Dr. John B. Hamilton, Surgeon-General U. S. M. H., Washington; Dr. Herbert H. Judd, Galesburg, Ill.; Dr. J. G. Carpenter, Stanford, Ky.; Dr. H. R. Storer, Newport, R. I.; Dr. J. B. Lawrence, New York; E. J. Hirsh, Ann Arbor, Mich.; Dr. Hubert S. Johnson, Lowell, Mass.; Dr. C. S. Pixley, Elkhart, Ind.; Dr. Wm. C. Banc, Cannonsburg, Pa.; Dr. D. Mason, Spokane Falls, Wash. Ter.; Dr. F. Terrier, Paris, France, Surgeon-Major Chas. D. Greenleaf, Washington; Dr. Mary Green, Charlotte, Mich.; Dr. C. T. Kemmurer, Eldridge, Ia.; E. Steiger & Co., New York; Hon. W. P. Sheffield, Newport, R. I.; National Surgical Institute, Indianapolis, Ind.; Dr. Wm. Perrin Nicholson, Atlanta, Ga.; W. M. Thayer & Co., Chicago; Geo. S. Davis, De-

troit, Mich.; Dr. J. G. Carpenter, Stanford, Ky.; Dodd's Advertising Agency, Boston, Mass.; Dr. T. A. Marchaud, Cincinnati, O.; Dr. A. N. Bell, Brooklyn, N. Y.; W. P. Cleary, New York; Medical College of Ohio, Cincinnati, O.; Dr. P. O. Hooper, Little Rock, Ark.; Dr. S. Solis-Cohen, Philadelphia, Pa.; J. H. Bates, New York; Longmans, Green & Co., New York; Fred. D. Van Horen, New York; Dr. W. E. Casselberry, Chicago; Dr. C. O. Cooley, Madelia, Minn.; Dr. G. B. Dunmire, Philadelphia.

### *Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 31, 1889, to September 6, 1889.*

By direction of the Secretary of War, a board of medical officers, to consist of Col. Edward P. Vollum, Surgeon; Major Henry McElderry, Surgeon; Major Washington Matthews, Surgeon; Capt. James C. Merrill, Asst. Surgeon, is constituted to meet in New York City on the 1st day of October, 1889, or as soon thereafter as practicable, for the examination of Asst. Surgeons for promotion and of candidates for admission into the medical corps of the Army. The board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General. Par. 1, S. O. 203, A. G. O., September 2, 1889.

Major P. J. A. Cleary, Surgeon U. S. Army, is hereby granted leave of absence for two months on surgeon's certificate of disability. S. O. 59, Hdqrs. Div. of the Pacific, San Francisco, Cal., August 27, 1889.

Capt. Joseph Y. Porter, Asst. Surgeon, resignation has been accepted by the President, to take effect August 29, 1889. Par. 11, S. O. 200, Hdqrs. of the Army, A. G. O., August 29, 1889.

Capt. Charles B. Ewing, Asst. Surgeon, granted leave of absence for twenty-one days, to commence on or about September 21, 1889, provided that at that time the post surgeon, now on leave, has returned to duty. Par. 5, S. O. 201, Hdqrs. Div. of the Atlantic, Governor's Island, N. Y., September 4, 1889.

First Lieut. W. B. Banister, Asst. Surgeon, granted leave of absence for fifteen days. Par. 2, S. O. 82, Hdqrs. Dept. of Ariz., Los Angeles, Cal., August 23, 1889.

The garrisons of Ft. Laramie, W. T., Ft. Hays, Kan., and Ft. Lyon, Col., will be withdrawn and the posts named will be abandoned as soon as it can be done with due regard to economy. By G. O. 69, A. G. O., August 31, 1889.

### *Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 7, 1889.*

P. A. Surgeon F. S. Nash, detached from the "Dale" and ordered to duty in the Bureau of Medicine and Surgery.

P. A. Surgeon A. C. H. Russell, ordered to naval hospital, Yokohama, per steamer of September 28.

P. A. Surgeon C. H. H. Hall, detached from naval hospital, Yokohama, on reporting of relief, and return home.

Asst Surgeon S. S. White, detached from naval hospital, New York, and ordered to the "Minnesota."

Asst. Surgeon E. P. Stone, detached from the "Minnesota," and wait orders.

Asst. Surgeon P. H. Bryant, detached from the "Ajax," and ordered to naval hospital, Norfolk, Va.

Asst. Surgeon A. R. Wentworth, detached from naval hospital, Norfolk, Va., and wait orders.

### CORRIGENDUM.

In the address of the Hon. Wm. P. Sheffield, appearing in THE JOURNAL of August 24, the closing sentence of the third paragraph, second column, page 253, should read: "He came while the court was in session, and after the trial and sentence of Mrs. Hutchinson."

### NASAL BACTERIA IN HEALTH.

*Read in the Section of Laryngology and Otology at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY JONATHAN WRIGHT, M.D.,

OF BROOKLYN, N. Y.

The position which microorganisms will ultimately take in their relation to the morbid processes of disease has not been determined as yet. Indeed, we seem now only at the beginning of an unknown region in which, possibly, lies hidden the mystery of the etiology of many pathological changes. Encouragement in the region of preventive medicine, under which head we must include all that Listerism has done for surgery, lends zest to the attempts to follow the microbe into the human organism and there annihilate. The almost complete failure thus far has given professional cynics an opportunity for a somewhat galling criticism. These failures are, no doubt, in a large measure due to our as yet very incomplete knowledge of the varying conditions and influences which complicate the relations of microbes to the human organism. Whatever opinion the clinician may have of the part played by them in the etiology of the diseases he observes, even the most skeptical must admit that the burden of disproof must have been thrown upon the doubters.

With the increased probability that many pulmonary and nasal diseases owe their origin, in a large degree, to microorganisms, it becomes important that the bacterial contents of the respiratory tract, in a state of health, should be known. Before we are in a position to investigate a pathological process, we must have a firm physiological basis on which to stand. Before we seek for a pathogenic microorganism in disease we should know what exists in the situation in a condition of health. The *ingress* of all infective agents must, in the vast majority of cases, be through the nose or the mouth: those of the respiratory tract, as a rule, through the former; those of the alimentary tract, as a rule, through the latter. The bacterial contents of the mouth, in health, have been so thoroughly investigated by Biondi,<sup>1</sup> Vignal,<sup>2</sup> Netter,<sup>3</sup> Fraenkel<sup>4</sup> and others,

that further researches would seem superfluous when our knowledge of the nasal microorganisms in health is so slight. As laryngologists we are becoming more and more impressed with the necessity of normal nasal respiration and the harm of mouth breathing. In the further advance of nasal bacteriology we may find another reason to urge the importance of purely nasal respiration. When we remember the apparatus of Hesse<sup>5</sup> for air analysis, the configuration of the internal nose would seem admirably adapted to arrest the progress of microbes carried into it by the air current; and still further, it has been conclusively proved that bacteria never rise from a damp surface, however strong the blast may be over it, unless carried along by some particle of water, or mucus, or solid matter. Hence we should expect to find innumerable varieties of bacterial forms derived from the air, and might well despair of reaching any definite conclusions in the matter. Besides the bacteria of phthisis and pneumonia and the microbe of diphtheria, whether it be the bacillus of Löffler or the streptococcus of Prudden, there seems good evidence that some purely intra-nasal diseases depend upon microorganisms for their origin or their subsequent course. A perusal of the researches of Löwenberg,<sup>6</sup> Klammann,<sup>7</sup> Thost,<sup>8</sup> Seifert,<sup>9</sup> Strauch,<sup>10</sup> Valentin,<sup>11</sup> Hajek,<sup>12</sup> Reimann,<sup>13</sup> and others into the etiology of ozæna and coryza must convince us of the truth of what Walb<sup>14</sup> says of ozæna. "I am convinced," he says, "that the way opened by Löwenberg will lead to the discovery of the nature of ozæna. Whether the Löwenberg cocens or some other is the cause of ozæna is of no consequence; it must exist and it is to be hoped that it will be found."

Whether there is a bacterial connection between coryza and pneumonia as claimed by Thost<sup>15</sup> and further urged by Cardone,<sup>16</sup> it is impossible, with our present knowledge, to form any opinion. Notwithstanding the abundance of literature to be found on the bacteria of nasal diseases, there is very little, in fact no, systematic examination of the normal nasal secretions for bacteria recorded in the somewhat extended range of literature to which I have had access. However instructive the staining of nasal secretions for bacilli and cocci, as a matter of technique, may be, there is

little or nothing else to be learned from it without the aid of the improved methods of culture tests. I have therefore omitted extended reference to this class of work. The mere presence of microorganisms in nasal secretions was established many years ago. Bernard Fraenkel, in Ziemssen's *Encyclopædia*, in 1876, in his article on "Acute Coryza," says: "A large number of these little structures recently so much spoken of and called micrococci, may generally be seen also covering the cells." And he refers to Hueter<sup>16</sup> as claiming these bodies to be the source of irritation in coryza. Herzog<sup>17</sup> in 1881 found many bacilli and cocci in normal and abnormal nasal secretions, more abundant in the latter, and especially in fetid nasal catarrh. Eugen Fraenkel,<sup>18</sup> on the other hand, in 1882, stated that he could find no bacteria in the normal nose, and his work on *Ozæna*, in the secretions of which he found four kinds of bacteria, has been widely quoted, but in the light of our present bacterial knowledge it possesses on this point only historical interest. Later observations have all been made incidentally in connection with bacterial investigations of disease. Bernard Fraenkel,<sup>19</sup> in 1886, found in the normal pharynx, besides the staphylococci *pyogenes aureus* and *albus*, a micrococcus which often appeared as a diplococcus, and did not fluidify gelatine. Probably the same coccus was found in the normal retro-pharynx by Hack,<sup>20</sup> and fully described by his pupil, Strauch.<sup>20</sup> The latter asserts that it is also found in the nose, but less frequently and in fewer numbers. Both Löwenberg<sup>21</sup> and Hajek<sup>12</sup> failed to find microorganisms at all constant or abundant in normal nasal secretions. Reimann,<sup>13</sup> on the other hand, described two forms as nearly always found; one a plump round ended bacillus, and the other a little coccus which occurred usually in pairs but often in longer chains. Considering the extensive and very thorough work done upon the bacterial contents of the mouth in health, it is singular that there should be such a lack of it in the nose.\*

My own observations were made during the last two years in the laboratory of the Alumni Association of the College of Physicians and Surgeons, under the direction of Dr. T. M. Prudden, to whose kindness and careful oversight the little which may be of value in them is due. The material was drawn from the Dispensary of the Roosevelt Hospital. Although a number of other cases were examined, it is my purpose to record here only those investigations made in fairly normal cases, leaving the examinations in the other

cases for further amplification and another occasion. The method of work was as follows: Portions of the nasal secretion were removed from the mucous membrane covering the turbinated bones and adjacent portions of the septum, in the loop of a long platinum needle previously sterilized in the flame. This was immediately plunged into two gelatine tubes and streak cultures were made upon two agar-agar plates. Thus four inoculations were made from different portions of the nasal chambers in each case. Besides this a number of dry cover-glass preparations were made of the nasal secretion in each case, and stained by Gram's method and by simple double staining. These last frequently showed no bacteria when the culture-tests proved their presence in great abundance. The gelatine tubes were plated according to Koch's method, and pure cultures obtained and transferred to culture media tubes of agar-agar, 5 per cent. glycerine-agar, gelatine, bouillon, milk and potatoes. The same was done with pure cultures obtained from the streak cultures on the agar-plates. The growth characteristics were noted and compared with description in the works of Flügge, Fraenkel, Eisenberg, and others, and where close correspondence was observed their denominations were accepted. Those forms found not to correspond to any description were, as a rule, carefully worked out and the records preserved, but it is unnecessary to describe them here, as they were only found in isolated cases. All the usual precautions were taken against contaminations, and, in addition, only those colonies selected from the plates which were in sufficient numbers to preclude the possibility of contamination and to eliminate, as far as possible, those microbes which had only recently become nasal inhabitants and had not yet grown in the nasal secretions to any considerable numbers. When one remembers the multitude of air bacteria which would naturally lodge against the nasal mucous membrane, and be only accidentally visitors to a soil unsuited to them, this precaution will not seem uncalled for. In all cases care was taken to ascertain that no nasal douches of any kind had been previously used. Any one, even those unfamiliar with the technique of bacterial analysis, will appreciate the amount of work required where so many different forms had to be carefully worked out; and that may be pleaded as an excuse for the limited number of cases brought forward. In the ten cases mentioned the condition of the mucous membrane was as nearly normal as possible, and even where insignificant changes were observed they are noted. The class of cases were not as diversified as could be desirable, as they were all dispensary patients. I made several bacterial analyses of the air of the Dispensary from time to time by Petri's and Sedgwick's methods, and by exposure of agar plates. At no time was there any growth but those of

\* At the last meeting of the Russian Congress in St. Petersburg, Besser reported having examined the nasal secretions of 81 patients, the bronchial secretions of 10, and the secretions of the frontal sinuses in 5. Out of the nasal and bronchial secretions he cultivated the Fraenkel-Weichselbaum diplococcus of pneumonia in 14 cases, the staphylococcus *pyogenes aureus* in 14 cases, and the streptococcus *pyogenes* in 7 cases. Unfortunately, I have not been able to procure the original article and the reference in the *Centralblatt für Bakteriologie*, Bd. V, No. 21, is incomplete, not giving the conditions under which they are found.

simple air bacteria noted. The nasal bacterial forms were found to vary markedly with the state of the weather and of the streets. High winds and dry and dusty streets were sure to fill the noses with air bacteria. In rainy weather, or after several days of calm, or when snow was on the ground, aerial forms were much more rare. It seems to me there can be only one cause for this, viz.: They tend to disappear because they have found a soil unfitted for their growth, and, according to the universal law of natural selection, give way to microbial forms more favored by the conditions. It certainly is not because they flow away in the secretions, because it is not only their absolute frequency which varies, but their frequency relative to other forms. The reaction of the secretion of the normal nose was found to be neutral or slightly alkaline.

*Case 1.*—Young man in fair health with exception of slight cough. No pulmonary lesion; slight hypertrophy of one turbinated bone; nose otherwise normal. A short plump bacillus, looking at times like a diplococcus; slow white growth on gelatine, which it does not fluidify. Same on agar, spreading slightly on surface.

*Case 2.*—Young girl with slight tonsillar enlargement; nose normal; general health good. Bacterial analyses were made on three separate occasions, and twice was found a nearly pure culture of the staphylococcus pyogenes aureus. The tonsils were examined and the same growth found there. Inoculations of pure bouillon cultures in the jugular of rabbits set up purulent pericarditis and endocarditis, of which the animals died. The pus swarmed with the cocci.

*Case 3.*—Boy of 17, who had a perforation of the septum and hard palate from a syphilitic process. All ulceration had long healed and the mucous membrane was normal in appearance. The staphylococcus pyogenes aureus was found in large numbers, and a moderate growth corresponding to the bacillus lactis aerogenes.

*Case 4.*—Man of 35. A few weeks previously had been discharged from Roosevelt Hospital after a severe operation for the removal of a thyroid tumor. The wound had healed by first intention. Left laryngeal paralysis resulted. The nose was perfectly normal in every way. The staphylococcus pyogenes aureus and albus were both found and abscesses caused by the injections of pure bouillon cultures of each beneath the skin of rabbits. From these abscesses new cultures of the same growths were obtained in each case.

*Case 5.*—Child 10 years old. No subjective nasal symptoms, but the mucous membrane of the nose is slightly hyperæmic. In this case also both the staphylococcus aureus and albus were found, and positive results obtained from animal inoculations.

*Case 6.*—A seamstress aged 16. She had had considerable post-nasal catarrh but no purulent

secretion. Nose normal and health good. Two examinations six weeks apart were made. Each time in the nares was found abundant growth of the ordinary mould, the penicillium glaucum. Each time pure cultures were obtained from the post-nasal space of the streptococcus pyogenes. A pure bouillon culture was injected beneath the skin of rabbits' ears and an erysipelatos inflammation produced, from the sanious pus of which cover glass preparations were made showing abundant cocci in chains. At the second examination a culture of a gas-producing bacillus was also made from the tonsils. The most careful questioning could elicit no history of exposure to contagion of any kind. She herself was in the best of health except the discomfort from her post-nasal catarrh.

*Case 7.*—Girl, aged 16; cigarette maker. There was slight hypertrophy of the nasal mucous membrane and some tonsillar injection. The staphylococcus pyogenes citreus was found in the nose.

*Case 8.*—Child, aged 4. Slight post-nasal catarrh and slightly enlarged tonsils. Nose normal. In it was found the micrococcus flavus desidens.

*Case 9.*—Man, aged 19, with follicular tonsillitis and post-nasal catarrh. This case presented considerable structural change, and I insert the record here because, in spite of the large amount of secretion present, only aerial forms were found. They were the micrococcus flavus desidens and micrococcus cereus flavus, and an undetermined coccus with a curious growth on agar and gelatine, a description of which would be out of place here.

*Case 10.*—Woman, aged 20, with slight attack of laryngitis. She was recovering from coryza, and there was some mucus secretion in the nose. The bacterial contents were as follows:

1. Staphylococcus pyogenes aureus.
2. Micrococcus flavus desidens.
3. A tetrad resembling closely the descriptions of the micrococcus tetragenus.
4. An undetermined coccus, with a white non-fluidifying growth on gelatine and agar.

Cases.	Staphylococcus pyogenes aureus albus and citreus.	Micrococcus flavus desidens.	Bacillus lactis aerogenes.	Penicillium glaucum.	Micrococcus cereus flavus.	Micrococcus tetragenus.	Different undescribed forms.
1	1	1	1	1	1	1	1
2	1	1	1	1	1	1	1
3	1	1	1	1	1	1	1
4	1	1	1	1	1	1	1
5	1	1	1	1	1	1	1
6	1	1	1	1	1	1	1
7	1	1	1	1	1	1	1
8	1	1	1	1	1	1	1
9	1	1	1	1	1	1	1
10	1	1	1	1	1	1	1
Total, 10	6	3	1	1	1	1	3

The three last cases were examined during windy, dusty weather, and illustrate well, espe-

cially in the last case, the unreliability of cover-glass preparations alone of the nasal secretions in determining bacterial species, as the morphological appearance in four out of the five organisms was the same.

To summarize :

In six cases, the staphylococcus pyogenes.

In three cases, the micrococcus flavus desidens.

In one case, bacillus lactis aerogenes.

In one case, penicillium glaucum.

In one case, micrococcus cereus flavus.

In one case : Micrococcus tetragenus.

Once in each of three cases : Different undescribed forms.

The air forms may be dismissed without further consideration. The micrococcus tetragenus found in only one case and in few numbers, need only receive a passing mention. In Case 6 the only organism in the nasal chambers proper, which was made out by two careful examinations at different periods, was the ordinary mould, the penicillium glaucum. It was in such great numbers that it possibly may have overshadowed the growth of other forms. Considering its great aerial frequency, it is singular that it was not more often found. In this case the streptococcus pyogenes was twice found in the naso-pharynx, which was the seat of a chronic catarrhal inflammation, but which showed few changes in the mucous membrane besides the reddening of the surface and the increased secretion of mucus. For its pathogenic significance in the air-passages the works of Netter,<sup>5,22</sup> Prudden<sup>21</sup> and others may be referred to.

Our attention is therefore directed to the staphylococcus pyogenes; the three varieties, aureus, albus and citreus, need only be considered as one in their pathogenic significance. We know as yet too little concerning the conditions under which this organism exerts its characteristic influence, to draw conclusions. It may be well, however, to refer to the statements of a few of the various workers in this field.

Ullmann<sup>23</sup> found the staphylococcus in the air in different situations and under varying conditions, as well as in the water of the river Spree. He and others found it in the earth, on the streets and on the walls of various rooms and buildings. As to man, he says, "Fürbinger found it in the dirt under finger-nails, and Bumm in the folds of the nipples. Biondi obtained cultures of it from the saliva, and Fraenkel from the tonsils. I have found it not only on the buccal mucous membrane, in the saliva, the tonsils, the pharynx and vagina of healthy people and of animals, but in the œsophagus, intestinal tract and bladders of recently killed animals. Lustgarten and Manna-berg found it constantly in the urethra. These investigations show that the staphylococcus is very widely distributed, and that it is found wherever living beings are."

From this we see that its very frequent occurrence in the nose forms no exception to the rule. It will require investigation of many more cases than those here cited to prove that it is the most frequent and abundant microorganism in the nasal chambers. Netter,<sup>22</sup> in speaking of the influence of pathogenic microorganisms in the mouth, nose and ears, says : "The presence of the microbes is not enough. It is necessary that they should be present in sufficient quantity to triumph over the resistance which healthy anatomical structures offer them. It is necessary that their virulence should be sufficiently great, and we know that their virulence is not always the same."

He might have also said that the resistance offered them is not always the same. On this head the work of Bujwid<sup>24</sup> is suggestive. He found that in round numbers a billion staphylococci aurei for a rabbit, a hundred million to a billion for a rat, and a hundred million for a mouse, could be injected beneath the skin of a healthy animal without result, no abscess forming.\* When, however, grape sugar had previously been introduced into the animals' system they succumbed. Ribbert<sup>25</sup> and his pupils, Fleck<sup>26</sup> and Laehr<sup>27</sup>, caused a catarrhal inflammation of the bronchi, with more or less a broncho-pneumonia, by injection of pure cultures of the staphylococcus into the trachea. Their investigations, as well as those of Wysskowitzsch,<sup>28</sup> tend to show that the lungs or the adjacent bronchial lymphatic glands, act as a sort of filter or as a place of destruction for the microbe, preventing their further penetration into the human organism.

Prudden<sup>21</sup> repeated the experiments of Fleck and Laehr with like results; he also succeeded in causing broncho-pneumonia by injections of pure cultures of the streptococcus diphtheriæ and by injections of ammonia.

Lübbert<sup>28</sup> caused fibrino-purulent tracheitis and bronchitis by injections of a pure culture of the staphylococcus into the trachea. It is asserted by many investigators, and their assertions are based upon extensive experiments, that it is the pavement epithelium which prevents the entrance of the various microbes into the subjacent structures and thence into the general system. The very general experience of laryngologists would hardly bear this out as regards the staphylococcus, since tonsils and uvulæ are cut without fear of septic invasion, and in all the operations upon the mucous membranes of the mouth and nose this is the least danger we fear. If, however, a patient bites the operator's finger so as to break the skin, unless the wound is thoroughly washed out with an antiseptic, local suppuration often

\* Since this paper was written, the very valuable papers of Buchner (Centralbl. f. Bact., iv, 25, and v, 1), and Nissen (Zeitsch. f. Hygiene, vi, 3), have come under my observation. They give convincing proof that it is the albumin in the blood plasma that exercises the destructive influence on bacteria in the circulation.

follows, and occasionally, from this, general sepsis.

I have mentioned the above facts and observations in order to show how little we as yet know and how vastly much more we have to learn about this comparatively well-known microbe so often found in the upper-air tract of healthy people. Before closing this already too extended contribution, I wish to make mention of some investigations, as yet very incomplete, which I have been engaged upon during the last two months, more in the hope that others with more leisure and better opportunities will continue them, than from an expectation of adding much to our knowledge. I refer to the nasal chambers as a bacterial filter of the air passing through them.

It has been definitely proven by the investigations of Grehant,<sup>30</sup> Paulsen,<sup>31</sup> Aschenbrandt<sup>32</sup> and Bloch<sup>33</sup> that the nasal chambers are not only warmers and moisteners of the inspired air, but act also as a filter for fine dust particles. The latter observer experimented with many substances in fine powder, and came to the following conclusion, as did Grehant and Aschenbrandt: "A certain part of all kinds of dust, even the finest, is held back; the larger part of the formed substances which float in the air do not reach the entrance of the larynx, or even the choanæ, but it is impossible for the nose, even with the help of the naso-pharynx, to *completely* free the air even from the coarser kinds of dust."

Now a bacterium, whatever its relative proportions to other divisions of matter with which we are familiar, is a ponderable substance, heavier than air, water or any of the animal fluid secretions. It is therefore subject to the same physical laws. It is yet an unsolved mystery how the bacillus tuberculosis reaches the most frequently chosen seat of its selective action in the apices of the lungs and how the pneumococcus usually reaches the lower lobes before we have lobar pneumonia. To a bacteriologist it is almost inconceivable how a microbe entering the anterior nasal meatus with the tidal air should go through the tortuous, moist passage of the nose, past the broad surface of the palate and the post-pharyngeal wall into the larynx, between the false and true vocal cords, down the long tubes of the trachea and bronchi, and finally find a lodging place on the walls of the bronchioles and air-cells. The chances of its being arrested before it reaches them seem almost infinite, especially since the tidal air must stop at a comparatively high point in the respiratory channel in inspiration, and flow upwards again on expiration. Neither does it seem probable that becoming arrested at some higher point it flows downward with bronchial secretions, when we remember the ciliated epithelium and its function. The lymph channels have been strongly urged as an explanation, but, although our knowledge of the pulmonary lymphatics is very limited, there are many objections to this vague theory which will occur to every one. The day for theorizing has gone by. A theory now-a-days should be considered as little better than confession of ignorance. However small and insignificant an addition to our knowledge, the ascertaining of the capacity of the nose as a place of arrest for microbes may be, it seemed so easy of demonstration that I have attempted it. The technical difficulties were many, but have been fairly overcome, though it needs a much more extended and varied research than I have yet made to draw conclusions. The task is easily stated: Ascertain the bacterial contents of the air before and after it has passed through the nose. Glass tubing of a calibre of  $\frac{1}{8}$  to  $\frac{1}{4}$  of an inch in diameter and 6 inches long was filled with granulated sugar for  $3\frac{1}{2}$  inches of its length, held in place at the bottom by a piece of rolled copper gauze, tightly fitting the tube, leaving enough space at each end for the insertion of a cotton plug. The sugar grains were of a uniform size of forty to the inch. This part of the apparatus was copied from that of Professor Sedgwick and G. R. Tucker, of Boston, to whom I am greatly obliged for a description of their method of air analysis, kindly sent to the College Laboratory some time before it was communicated to the Society of Arts, in whose proceedings for 1887-1888 it may be found. Their rules for sterilization of the sugar and the apparatus were also followed. For reasons which I need not stop to explain here it was found best to vary their procedure considerably and adopt, to some extent, the method of Petri,<sup>34</sup> with sand. After proper sterilization the glass tubing was attached, by means of stiff rubber tubing, to an air-exhaust apparatus. As there was a good head of water in the laboratory a Sprengel's air-pump was principally used, by means of which one litre of air could be drawn through the  $3\frac{1}{2}$  inches of sugar in from forty seconds to one minute. Usually, however, a very perfect air-exhausting apparatus may be obtained by making use of the Allen Surgical Pump, of the size used for veterinary purposes, which I show you here, in connection with the air filter. About one hundred revolutions of the handle of this instrument, which can be made in forty-five seconds, or a minute, will exhaust one litre of air. With either contrivance it is perfectly easy to ascertain the rate at which air will pass, by means of a litre-flask inverted in water. It has been proved by Sedgwick, and I have verified the statement, that air passing at about this rate will deposit all its bacterial contents in the sugar.

With this apparatus, then, 10 litres of air are drawn through the filter after the cotton plugs used during sterilization have been withdrawn. Then 10 litres of air at the same time and in the same locality are drawn through the nose and also through the filter. This is accomplished as

follows: The glass tubing with its load of granulated sugar, all thoroughly sterilized, is enclosed by means of a perforated rubber cork in a larger piece of glass tubing and the space between the two loosely packed with absorbent cotton. The end of the smaller tube does not reach to the end of the larger. The filter thus protected from the bucal secretions is put in the mouth and the lips closed firmly around the outside tubing. If held in a horizontal position in the mouth nothing but air can enter the filter when the suction is begun. During alternate periods of fifteen seconds each the person is directed to hold his breath, making the thoracic walls rigid. Thus practically all the air drawn through the filter must have first passed through the nasal chambers and the post-nasal space. During the fifteen seconds of respiration the air-current is shut off by compressing the rubber tube between the filter and the suction apparatus, consequently the time consumed in the examination of the nasal air is twice that consumed in the control examination. The plan adopted by Aschenbrandt and others of drawing the air up one nostril and down the other before examination, besides other faults, permits the entrance of mucus into the air filter, which it is impossible to protect from contact with the walls of the nasal chambers.

After the 10 litres of air are drawn through in each case the sugar is dampened and partly dissolved with a few drops of carefully sterilized water to facilitate its removal from the glass tubing. By means of a sterilized, stiff brass rod the wire gauze is pushed along the tubing, forcing the wet and partly-dissolved sugar out into shallow glass dishes, where it is thoroughly dissolved and mixed with 10 per cent, nutrient gelatine. The glass tubing is filled with gelatine and stopped at both ends with cotton. The gelatine in the dishes is allowed to solidify slowly, so as to insure the complete dissolving of the sugar. It was found that very few, in many cases no colonies developed in the glass tubing, so completely did the sugar carry along its bacterial contents with it when pushed out. I have described the process hurriedly and omitted descriptions of the routine precautions taken in sterilizing, controlling and guarding against aerial contaminations which belong to the technique of careful bacterial analysis.

The colonies developed after several days in the two sets of dishes were counted and compared. As I said before, too few examinations were made to arrive at hard and fast conclusions. I only experimented on my own nose, and have succeeded only recently in getting results free from errors of technique. Speaking in a general way, the nasal chambers in my own case seem capable of filtering out about three-fourths to four-fifths of the bacterial contents of the air passing at the rate of one litre per minute. The photographs

of an examination made during the presence of a considerable quantity of mould in the air, illustrate this fairly well. This particular experiment was photographed because the white moulds show the difference in a more striking manner than bacterial colonies, but the same proportion seems to hold good with them, as for instance, in an examination made April 25th of this year:

Ten litres of laboratory air contained 4 moulds and 125 bacteria.

Ten litres of laboratory air after passing through nose contained 1 mould and 24 bacteria.

Of course noses must differ in this respect as in other ways, and the rapidity of the current we know makes a difference in the number of both moulds and bacteria deposited in Hesse's apparatus. Counting 500 cc. as the tidal air with each inspiration, we have about nine litres per minute passing through the nasal chambers in normal respiration. In the experiments just mentioned the rate was only a little over one litre per minute. In spite then of the apparently well-adapted arrangement of the nasal chambers for a bacterial filter, even at this rate, a really large number of bacterial forms are carried at least into the larynx. It is to be hoped that further and more complete and reliable investigations will confirm or refute this somewhat premature assertion. Unless we throw aside the very numerous and careful observations made by bacteriologists in pulmonary diseases as useless, it is surely of the greatest importance that we should know something of the mode of ingress of microbes into the deeper pulmonary tracts.

DR. JOHN MCKENZIE, of Baltimore, thought the solution of many points in nasal pathology by bacterial investigation would not be an event of the immediate future. The problem is an intricate one, especially in view of the constantly changing environment of the individual. The dependence of ozena on micrococci has not been determined.

## THE IMPORTANCE AND ESSENTIAL NEEDS OF LOCAL BOARDS OF HEALTH.

*Read in the Section of State Medicine, at the Fortieth Annual Meeting of the American Medical Association, June 25, 1889.*

BY WILLIAM C. RIVES, M.D.,

FORMERLY SECRETARY BOARD OF HEALTH, NEWPORT, R. I.

Although much has been said and written upon the subject of local health organizations, the indifference which is still widely prevalent in our country, outside of the large cities, in regard to the necessity for the formation and proper administration of such bodies, and the great intrinsic importance of the question itself, furnish some reasons for additional remarks.

The protection and preservation of health through measures taken against those dangers which threaten it from preventable causes is a subject which not only concerns sanitarians but also every member of a community, and as these measures must necessarily depend chiefly upon the local board and its health officer, the value of efficient boards of health cannot be overestimated if the advantages of sanitary measures are to be regarded at all. It is, indeed, unnecessary to remind any intelligent man who has paid the least attention to sanitary science of the importance of local boards of health; yet, while all thoughtful persons appreciate the need of them, there are many communities which are not alive to this necessity, as is evinced by their unwillingness to have a local board, or else by their failure to confer sufficient powers upon it or to contribute their hearty support after it is established.

It is, notwithstanding, a matter settled beyond the possibility of question, no longer admitting of argument, that the proper enforcement of suitable health regulations and due attention to sanitary requirements have achieved most striking results in reducing the general death-rate, and in limiting especially the prevalence of the zymotic diseases and of others whose occurrence is facilitated by local uncleanness or unsanitary conditions. Through the exertions thus made for the prevention of disease, other advantages have ensued. The aid afforded by the application of sanitary principles in promoting the advancement of Christian morality by improving the condition of the wretched abodes of the poor in the large cities and by the prevention of overcrowding is of incalculable benefit; the saving of expense which has been often estimated in particular instances, is perhaps not too strongly expressed in the lan-

guage of Mr. Gladstone in one of his addresses: "There is no greater economy than the saving of human life."

It is needless for me to quote from the enormous mass of statistics to show the actual good that has been done by the carrying out of sanitary reforms. These are particularly striking in the case of England, the foremost country in the world in the care that is taken of the public health. The action of suitably constituted health authorities has made London the healthiest large city in the world, reducing the general death-rate, which for a number of years during the eighteenth century is said to have been not less than eighty out of every thousand, to twenty to the thousand, and has also throughout England accomplished analogous results. It has effected wonderful improvements in the British Colonies, where such cities as Bombay, Calcutta and Hong Kong have been freed from the terrible epidemics which formerly were liable to devastate them; and in other countries of Europe, and in our own land, it has accomplished much, although far from what is possible. Owing to the care that is now taken small-pox, yellow fever and Asiatic cholera are greatly restricted and no longer sweep uncontrolled through cities as in former times. In short, some of the greatest achievements of modern science have been in preventive medicine and, owing to the remarkable discoveries of Robert Koch and other bacteriologists, we are on the eve of restricting in some degree that dread disease, pulmonary tuberculosis, by taking precautions formerly considered unnecessary.

In cities, indeed, the advantages of proper sanitary administration are so obvious that they will not be disputed; but neither is it of little importance in smaller places and in rural communities. The intimate relations which exist between town and country at the present day not only render the sanitation of villages and rural districts a matter of importance to themselves, but also may be attended with far reaching consequences to others, which becomes evident when we recollect that most disastrous results may arise from neglect of sanitary precautions in some small village or obscure house. It was the disregard of these in the case of a single isolated dwelling which was the cause of the unfortunate epidemic at Plymouth, Pa. The great epidemic of typhoid fever in the parish of Marylebone, London, in 1873, was traced to a single case at a country farm which supplied milk to a dairy in that parish, directly occasioning no less than 218 cases of the disease, from which a very large number of additional cases originated. Since that time as many as eighty-one epidemics have been traced in various parts of that country to milk distribution.

Speaking generally, the ultimate object of all sanitary endeavor is to prevent the spread of infectious and contagious diseases, and to lessen or

remove influences injurious to health by securing the highest degree of cleanliness practicable and by exercising supervision over the air, food and water supply. In addition to this, there is the important matter of the registration of vital statistics. Now, to accomplish all that is needed for the attainment of these objects, the requirements which, in the complex conditions of modern life, are necessary, are so very numerous that they cannot be satisfied by the action of the ordinary local authorities as such, but give ample and varied scope for the work of permanent independent organizations, which should be given all the legal authority and means necessary for the due discharge of their office. While fully recognizing the great value of State Boards of Health in their proper sphere, it is to local boards that we must mainly look for the actual carrying out of the details of sanitary reform and the achievement of the direct and practical results required for the protection of the public health; so that the sanitary work of a State may be said to be, in the main, the sum of the work accomplished by its local boards, and in so far as the State boards succeed in influencing them to perform their duties, they will have fulfilled no small part of the purposes for which they were created. That there should be, therefore, a complete system of sanitary administration, boards of health should be established in every city, town and incorporated village, and in the less thickly settled States and where the necessity exists they should also be established for townships or counties.

Whether or not a single health officer with all the powers of a board may not in some cases be more desirable, I will not attempt to discuss. And yet outside of the large cities, where the necessity for them is so urgent and imperative that there are usually well constituted boards of health, although often suffering for the want of sufficient appropriation, in many of the States there has existed and does still exist, notwithstanding there has been of late much improvement, a most unsatisfactory condition of affairs, as may be seen by referring to Dr. Toner's paper on "Boards of Health in the United States,"<sup>1</sup> or the information upon this subject to be found in the reports of the various State Boards. It is surprising that the need is not more keenly felt, and yet it would seem as if an active board of health is often looked upon as a set of sanitary fanatics who involve a community in expense, annoyance and useless alarm, frightening away newcomers and involving every one in unnecessary trouble, opposition frequently coming from the very classes who need it most; for, as Sir William Jenner says, "the value placed by a community on individual life is one of the great tests of the state of civilization." The obstacles in the way of boards of health are in fact mainly due to the indifference, ignorance and prejudice on the part of

communities and of the authorities upon whom their appointment rests, which interfere with proper legislation and with adequate support of the board after its formation.

One of the principal reasons for this indifference and apathy is that the work done by boards of health being of a preventive nature, the results obtained are not at once appreciated by the public at their full value; since to estimate and demonstrate their worth, requires a very careful consideration of all the vital statistics and conditions of a locality. As Dr. Parkes has stated, "the establishment of the Registrar-General's office in 1838 and the commencement of the system of accurately recording births and deaths will hereafter be proved to be, as far as the happiness of the people is concerned, one of the most important events of our time." It sometimes happens, moreover, that, owing to the great natural advantages of a place and the absence of any serious epidemic, the general death-rate may be quite low, even for a number of years, without due attention being paid to sanitary requirements, and a community is not slow in seizing upon this as a reason for neglecting its duty. Sooner or later, however, there will be disaster, of which there were several instances in Newport a few years ago, notably as regards diphtheria, four and even six cases occurring in single houses. The frequent excuse that the general health of a community has been sufficiently satisfactory without stringent health rules is of no real weight, for the question is not so much how little sickness exists as whether any disease has prevailed that is preventable and whether, if proper measures had been taken, the death-rate would not have been still smaller.

Another reason for the prejudice against boards of health is the refusal to see that expert knowledge is required in sanitary matters. Instead of listening to those competent to give advice upon such subjects, communities and city councils are apt to consider themselves fully able to judge about all questions relating to the public health, and because they themselves are not convinced of the need of sanitary reform they conclude that the need does not exist, their attitude towards sanitary science reminding one of the sarcasm of Socrates regarding political science, that he supposed it could not be taught, since the Athenians, although asking the opinion of experts upon all other questions, when it came to politics appeared to look upon every man, however ignorant and uninstructed, as qualified to give advice. Another cause for the dislike is an unreasonable fear and jealousy that individual rights and personal liberty may be invaded by unnecessary rules and restrictions, but liberty is not license, and no man has a right to endanger the health and well being of his neighbors or of the community. Still another cause is that for political reasons the officers of many municipalities object to a separate board

of health, being unwilling to relinquish any particle of power. Thus it unfortunately happens that at the present time so many of the health departments, even of our large cities, are improperly organized and entrusted with insufficient powers.

To promote, therefore, the establishment of local boards of health and to render them efficient (for an inefficient board of health may be worse than none at all), there are various needs which must be satisfied, relating, 1, to the appointment and organization of the board; 2, the legal powers with which it is entrusted; and 3, the means by which its orders are carried into effect. First, the State law upon the formation of local boards should be mandatory, and if certain of the local officers are designated in it as members of the board—which, if allowable in small places, is certainly objectionable in cities, where the board should be as far as possible removed from the influence of local politics—it should be clearly specified that such boards must be distinct organizations with their own independent and peculiar duties and separate officers, who shall be regularly and formally elected. The experience of many of the States, Rhode Island among the number, shows that merely *ex officio* boards of health entirely composed of the local town or city authorities, without regular organization and definite duties, are incompetent to deal adequately with health problems; in ordinary times they are inactive, and when an epidemic comes they are usually unprepared and unable to act as the occasion demands.

With regard to the method of organizing an independent board, little or nothing can be added to what has been already said in the admirable papers of the late Dr. Leconte<sup>2</sup> and Dr. Lee.<sup>3</sup> The appointment of the members, when not designated in the State law, will usually rest with the City Council or town or village officers, and they should not be chosen by popular vote. They should be from three to seven in number according to the size of the place and, as a board of health should be a permanent body and may be expected to increase in efficiency from past experience, the terms of office should be for long periods and should not all expire at the same time; so that the membership, if changed at all, should only be done so gradually, leaving always a majority of old members. Those who are selected should be appointed, as far as possible, with a view to their fitness for the position. Too often this is utterly disregarded, and from local political influence the appointment is frequently made of men who are not only uninformed about sanitary

matters, but may even be indifferent or antagonistic to them and greatly obstruct the board's work. The words of John Stuart Mill, referring to this country, may well be borne in mind, when he spoke of the "incompetency and mismanagement arising from the fatal belief of your public that anybody is fit for anything." The board should elect a chairman or President and a Secretary, and it will be of advantage, when it is composed of five or more members, to appoint standing committees upon special departments of sanitary work. The health officer, upon whose efficiency the successful accomplishment of the measures directed by the board largely depends, should possess suitable qualifications, and a good salary should be attached to the office, that men of sufficient ability may be secured. He should usually be a physician unless none can be obtained, and should be appointed by the board, not by the local authorities. He should be present at its meetings but not vote.

It is an absolute necessity that boards of health should be given full power to enforce all sanitary ordinances and laws and have authority to arrest and punish any persons who may resist their legal orders or endeavor to prevent their being carried into effect. Various provisions are made in the different States for the legal enactment of health regulations. In some they must be adopted as ordinances in town meeting or by a City Council, who are, however, not always willing to do this. In others, like the State of New York, full power is given every local board to make regulations which shall be obeyed as laws. The law of the State of Maine upon this subject seems to me a very satisfactory one, viz.: that such regulations, after being adopted by the board, become legal on the approval of a Justice of the Supreme Court of the State. It is highly desirable that, as has been done in many States, there should be a general form suggested by the State Board for local ordinances; capable, of course, of modifications or additions. This will to a great extent silence criticism when it is known that similar regulations apply to all localities in the State. It is advisable that the regulations be not too numerous, as they are worse than useless if the local board cannot enforce them.

Local boards, even when legally authorized to enforce sanitary ordinances, do not always in practice find it easy to do so. In large cities boards of health have their own legal and police officials, and so are able to act with promptness. In smaller places the actual enforcement of the laws must be done through the ordinary local prosecuting and police officers, who must be definitely required to attend to violations of ordinances or regulations reported to them by the board without unnecessary delay. In places of sufficient size one or more special sanitary police will be of much assistance, and there should also be, whenever required, a suffi-

<sup>2</sup>"Sanitary Problems: The Proper and Rational Method in which Municipal Boards of Health should be Organized." By John L. Leconte, M.D. American Public Health Association Reports, Vol. iv, pp. 131-134.

<sup>3</sup>"The Proper Organization of Local Boards of Health." By Benj. Lee, A.M., M.D., Ph.D. First Report of Pennsylvania State Board of Health, p. 135.

cient number of inspectors and other officials for attending to the various necessary details of the work of the board. It is needless to say that a board of health is helpless without a sufficient appropriation.

It is a far easier task to point out the want of boards of health and their needs when established than to provide a remedy, but the main effort should be directed towards impressing upon the community in general and local authorities in particular the value of the results to be accomplished through boards of health, and so to educate the public that a separate health organization will be looked upon as much as a matter of course as a fire or police department.

There are several influences which will tend to create this desirable condition of affairs. First, as before said, if it can be obtained, let there be a State law, of which that of New York furnishes a good pattern, requiring the formation of separate local boards at least for cities and towns, for nothing short of this will succeed in overcoming the apathy manifested in some localities. In Connecticut, for example, five months even after such a law was in force, in 1887, such was the indifference that fifty towns had not organized their boards and reported their health officers to the State Board in compliance with the law, notwithstanding that they had been notified of their duty. The subsequent effect of the law, however, in that State has been most satisfactory. Let all the influence, then, of State Boards, sanitary protection associations, the press, physicians and clergy be exerted to obtain such legislation, and when this is unattainable let, at least in the separate towns, endeavor be made as far as possible to move the local authorities to action. The State Boards especially can do much towards securing proper legislation and can greatly assist the local boards by providing them with all the information they need, especially on their first organization. Great assistance may be rendered by sanitary protective associations. That of this city, the first organized in America, has exerted, in spite of a large amount of abuse and opposition, no small influence in securing a board of health and in interesting the community in sanitation. The influence and work of a local board can be greatly aided by the physicians of the place through their coöperation in checking the spread of infectious diseases and in assisting in the proper registration of vital statistics, in calling attention to sanitary requirements and in general support. In this connection I would refer to the paper by Dr. Bryant, of New York.<sup>4</sup> The press and clergy can also be of great help; and finally, the board itself, by its efficient work its tables of statistics, and care not to be unreasonably exacting, can gradually elevate the

public sentiment and attain to the position of importance which it ought to occupy.

The history of the city of Newport in its health matters will serve as an illustration of some of these remarks. Its celebrity and importance as a place of summer resort render a due attention to questions relating to the public health of peculiar importance to its prosperity. Attention has been repeatedly called to defects in its sanitary administration and the nuisances which were suffered to exist, by the late Dr. Marion Sims, by Dr. John C. Peters, by Mr. Bowditch in a report of a house to house inspection published by the National Board of Health,<sup>5</sup> by Dr. Storer, and also by the city Sanitary Protection Association, and the need was urged of a separate board of health; but the law of Rhode Island not requiring, but merely permitting the formation of independent health boards, the power to establish such a body rested entirely with the city board of aldermen. By petitions, representations, and the exercise of influence of various kinds, the aldermen were at last brought to see the advisability of a separate board, and accordingly in 1885 an ordinance establishing one was passed. This ordinance is not permanently in force, but requires to be reordained every year, and gives to the board limited powers, it having no authority to make, but only to suggest sanitary ordinances, while the city authorities still retain control over matters over which the board of health should properly exercise supervision; such, for example, as the disposal of garbage. The executive officer can only be nominated by the board, and is appointed by the City Council. The board has legal authority to abate nuisances and enforce regulations, but the means of promptly enforcing them seem as yet imperfect, apparently from a want of a thorough understanding and coöperation between the board and the city legal and police authorities. Nevertheless it has done good work in preventing the spread of infection and in keeping the public informed, by the tables it publishes, of the state of the public health. Where it has been least successful is in remedying the old leaking cesspool system of drainage and other similar evils, for which the city authorities are in no small degree responsible, as they have not yet passed an ordinance making sewer connections compulsory in the compact part of the city, notwithstanding this has been recommended in three successive reports by the board. The board has thus been impeded by want of proper legislation, as well as by the want of means to carry out reforms, but it is made up of competent members possessing the public confidence, and there are few in the city who would now wish to return to the old state of affairs.

It is to be hoped, therefore, that as the public both here and elsewhere become more fully convinced of the importance of the matter, this and

<sup>4</sup> How can the Medical Profession aid the Board of Health? By Joseph D. Bryant, M.D., Health Commissioner, New York. N. Y. Medical Record, November 12, 1887, p. 613.

<sup>5</sup> Report of National Board of Health, 1882, appendix C., p. 153.

other places in like condition may not long be destitute of what are so needful for their welfare, thoroughly efficient independent boards of health, with ample powers.

DR. HIBBARD, of Indiana, said that in new organizations there was generally an attempt to mark out too extensive a programme at the outset, and that in his opinion it was better to advance more slowly, to be active in these matters but conform to the character of the environments.

DR. SMART, U. S. A., expressed himself as in favor of activity and energy in these directions.

DR. MORRIS said that for his part he was greatly interested in the matter of plumbing and that, greatly to his surprise, he found in the hotels of Newport abundant evidence of neglect in this important matter.

DR. STORER, of Newport, replying to Dr. Morris, explained that while the Board of Health of Newport had done what it could, it was aware that some of the hotels had not yet adopted the suggestions of the Board.

### DIOSCOREA VILLOSA—WILD YAM.

*Delivered in the Section of Practice of Medicine, Materia Medica and Physiology, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY JOHN V. SHOEMAKER, A.M., M.D.,  
OF PHILADELPHIA, PA.

It is the writer's purpose in this brief paper to call attention to *dioscorea villosa*, a valuable plant, but one that is seldom employed by reason of the scant literature upon its medicinal action. It is my hope that if the short clinical experience which I have had in the past continues to bring good results, that in the future it may lead to further and better investigations upon this remedy.

*Dioscorea villosa*, a plant which is commonly known as wild yam or colic root, is found in profusion throughout the Southern and to a limited extent in the Northern and Western States. Thirty years ago it was enlogized by King, of the Eclectic School, as a true specific for bilious colic, no other agent being necessary in this disease as it gives, he reported, prompt and permanent relief in the most severe cases. This statement has been repeated many times since by the disciples of the Eclectic doctrine, and is undoubtedly true. The part of the wild yam used is the root, which is inodorous, but on bruising develops a slight woody odor. To the taste the root is somewhat pungent, sweetish and bitterish. It is pulverized with difficulty, yielding a yellowish gray powder. The root is soluble in both water and alcohol and contains an active principle known as *dioscorein*, which possesses nearly all the medicinal virtues of the root. A further analysis of the root would be of great advantage in studying this plant, as

well as an investigation upon the physiological and therapeutic action of the active principle. The want of time has prevented my giving attention to the all important consideration of this portion of the subject, which I hope to investigate, or see others do so in the future. I therefore regret I am not able to add in this connection the physiological action of this plant which still remains to be studied. The scope of the paper is limited to the clinical results so far experienced from *dioscorea*. The preparations of wild yam usually employed are a decoction, the dose being from one to four fluid ounces, a tincture, the dose from ten to sixty minims, and the fluid extract, the dose being about half of that of the tincture.

Large doses of any of the preparations named have produced emesis. From its action it has been classified by King as an anti-spasmodic. It acts likewise as a diaphoretic and has some expectorant properties. *Dioscorea* appears to have an especial effect upon the liver, as *nux vomica* has for the spinal cord. It is a most useful remedy in the treatment of the various diseases of the hepatic system. In that painful affection known as bilious colic, which is the result of the pressure or impaction of one or more gall-stones in the biliary ducts, *dioscorea* often affords great relief. The treatment usually recommended consists of the administration of copious draughts of hot water, a prolonged course of phosphate of sodium, the inhalation of chloroform, heroic doses of morphine, or a combination of turpentine and ether, and even with all these remedies we are told that the disease may persist for days and weeks. Yet as related by King thirty years ago, and as restated by Dr. Todd in the *Atlanta Medical and Surgical Journal* some two years past, every case of bilious colic can be cured in a brief period, varying from a few minutes to a few hours by the administration of *dioscorea* alone.

The only qualification necessary to this claim at present is that the cases must be of pure biliary nature due to the presence of a gall-stone or of thickened, hardened bile in the biliary ducts, and not cases of intestinal colic from other causes. A good rule in practice is to see if with the colicky pains and nausea there be also any yellowish discoloration of the skin or conjunctiva. If there is, *dioscorea* will usually give prompt relief; if there is not, it may have to be supplemented with other remedies. Even when the stage of incipency is passed, when the delicate lining of the ducts are engorged and inflamed, so that the bile cannot pass through, *dioscorea* will be found of infinite value in lessening the engorgement, relaxing the tension of the biliary channels, and cutting short the course of the disease. That indefinite complaint known as hepatic torpor or hepatic indigestion, resulting in dull headaches, loss of appetite, mental inaptitude, causeless melancholy, and a train of other symp-

toms, can be quickly and permanently relieved by the fluid extract of dioscorea taken in fifteen drop doses before meals. Of course if there be another cause at work, such as constipation, improper hours, ill-prepared food, excessive use of liquor or tobacco, etc., they must be removed or counteracted. If tonics are needed, they must be given in addition to the dioscorea. An excellent tonic containing dioscorea is as follows:

Take of fluid extract of dioscorea villosa, 1 ounce.  
Compound tincture of cinchona, 5 ounces.  
℞. Dose: A teaspoonful in water before meals.

In cirrhosis of the liver too much benefit must not be expected from any remedy. In spite of all our efforts the inexorable advance of the fibrous connective tissue, crushing out blood-vessels, biliary cells and nerves, can be retarded for only a short time. My experience leads me to hope that for this purpose dioscorea may be found more beneficial than the two-edged mercuric, bi-chloride, which is now so largely employed. In chronic congestion of the liver, characterized by fullness of the right side and an increased area of percussion dulness and a general impairment of the digestive functions, a marked improvement and a gradual cure may be obtained by the administration of from ten to forty drops of the fluid extract of dioscorea in water before meals. In those suffering from an over-indulgence in alcoholic stimulants, and in alcoholic catarrh of the stomach, no better remedy can be suggested than dioscorea. The following combination in the latter disease is of value:

Take of tincture of belladonna, . . . . . 24 drops.  
Tincture of nux vomica, . . . . . 1 drachm.  
Tincture of dioscorea villosa . . . ½ ounce.  
Syrup of ginger, . . . . . 2½ ounces.  
℞. Dose: A teaspoonful in water every 4 hours.

In chronic malaria great benefit can be derived from the use of dioscorea alone or in combination with other remedies. A prescription of service in this affection is appended:

Take of solution of arsenite of potassium, 1 drachm.  
Tincture of dioscorea villosa . . . ½ ounce.  
Compound tincture of cardamon, 2½ ozs.  
℞. Dose: A teaspoonful in water after meals.

The following combinations containing dioscorea will also be of benefit in malaria:

Take of tincture of nux vomica, . . . . . 1 drachm.  
Tincture of dioscorea villosa . . . ½ ounce.  
Compound tincture of cinchona, 5 ozs.  
℞. Dose: A teaspoonful in water before meals.

Take of sulphate of quinine, . . . . . 20 grains.  
Tincture of dioscorea villosa . . . ½ ounce.  
Syrup of orange flowers, . . . . . 3 ounces.  
℞. Dose: A teaspoonful in water every 4 hours.

For preventing bilious headache, or modifying the attacks after they have appeared, dioscorea has proved of value. In intestinal indigestion, due to the lack of sufficient bile as manifested by the development of offensive gases, clay colored

stools and general mal-assimilation, remarkable benefit may at once follow the use of dioscorea combined with a little capsicum or strychnine.

Cancer of the liver is of course an incurable disease but more relief can be afforded to patients suffering from it by adding dioscorea to their morphine than by administering morphine alone. It is probable that dioscorea will be found of great service in the treatment of many other diseases totally unconnected with the liver. Its great power in relieving the spasm or contraction of the biliary ducts would indicate its use in various affections where anti-spasmodic remedies are requisite. Time and investigation alone can adequately measure its importance. I hope that the recital of my experience with it and the gratifying results it has yielded will induce others to test the efficacy of this valuable remedy. The following cases may be of interest showing the beneficial results from the use of dioscorea:

*Case 1.*—Mrs. A., aged 35, had been suffering from colic at times for eight months. The attacks lasted from eighteen to twenty-four hours and often recurred weekly. The pain was frequently intense and could only be temporarily allayed by whiskey and laudanum. Spontaneous relief was always preceded by vomiting after, as she tersely expressed it, "she was played out by the pain." On one occasion the pain was so violent that the attending physician, becoming alarmed, sent for me in consultation. On entering the room the yellowish hue of the patient's face, arms and neck at once attracted my attention. The conjunctiva was unchanged. On inquiry I learned that her color varied similarly with every recurrence of the colic, and gradually became normal after the subsidence of the pain. As this was the first case of biliary colic that I had seen since the publication of Dr. Todd's article, I determined to try the merits of dioscorea on it. I accordingly sent for one ounce of the tincture of dioscorea, and directed that the patient be given thirty to sixty drops every half hour until the pain lessened. On calling in the evening I was surprised and gratified to learn that the pain had disappeared with the third dose of the medicine and had not returned. I then ordered the remedy to be continued in the same doses every three hours, and instructed the attendant to search any evacuation that might occur from the bowels for gall-stone. When I returned the following morning I found the patient had passed a large gall-stone during the night and was able to be around attending to her usual duties. She continued the dioscorea for two weeks and has not had a symptom of colic or of ill-health from that time.

*Case 2.*—Miss M., aged 22, while lifting a tub of clothes was suddenly taken with a sharp pain in the right side which was greatly increased by attempts to take a full breath. Thinking that she had suffered some internal injury, she sent

for me. After making an examination of her chest I was unable to discover any indication of pleurisy or of a deep seated sprain, but as in the preceding case a peculiar brownish or yellowish-brown discoloration of the skin was found to be present. On being given a looking glass the patient admitted that there was something wrong with her complexion. It was then my opinion that this was a case of sudden obstruction from a gall-stone and would furnish a good opportunity to further test the value of dioscorea. I directed the patient's mother to give her thirty to forty drops of the tincture every two hours, and left the usual directions about having the evacuations searched for gall-stone. The pain disappeared after the second dose of the remedy, and during the night she passed two good sized gall-stones. In neither of these cases was the discoloration so marked as to simulate or resemble jaundice.

*Case 3.*—Mrs. C., aged 45, after exposure to wet and cold was seized with a sharp pain in the right side. The next day her eyes and skin had a yellowish-green appearance. I was sent for and pronounced the case jaundice, due to the presence of a gall-stone in one of the biliary ducts. I ordered her 30 to 40 drops of the tincture of dioscorea every two hours. On returning in the morning I found her much improved and inclined to doubt the correctness of my opinion that she had jaundice, for, as she truthfully said, she "had never heard of anybody being cured of jaundice in a day." Notwithstanding this good lady's opinion, I believe that there are many cases of jaundice due to the arrest and detention of gall-stones in the ducts, which if treated properly may be dissipated as promptly as followed in this case.

*Case 4.*—Mr. A., aged 25 years, has been subject for several months to "bilious attacks," lasting for three days and characterized by violent frontal headache, great loathing for food and obstinate constipation. On applying for relief on Christmas eve, he stated that all his symptoms were aggravated by the knowledge that he would not be able to eat any Christmas dinner. I assured him that his fear was unnecessary, that the attack would be cut short long before the dinner was prepared. I directed him to take three 30-drop doses of the tincture of dioscorea during the evening and two compound cathartic pills on going to bed, and to resume the dioscorea in the morning. He returned about a month afterwards stating that the medicine had worked like a charm, and asked for some more to ward off another attack. I renewed the same prescription and he has not had the slightest headache or any digestive trouble since that time.

*Case 5.*—Mrs. D., aged 37, informed me that she was suffering from "cramps of the womb," due to falling of that patient and long suffering organ. She was without doubt having severe

pain as the expression of her face and the contortions of her limbs gave evidence, but doubting her ability as a diagnostician, I asked her how she knew the cramps were caused by her womb being out of place. She replied that she had similar attacks on two previous occasions, for which she was treated, and that the cause of her suffering was prolapsus or falling of the womb. She added that on the first instance she was in bed for two weeks, and on the second for thirteen days. I made a vaginal examination and found that the uterus was markedly prolapsed, but that it was also free from pain, and I therefore concluded that her opinion of the former attacks was incorrect, and the seat of the disease was in some other portion or organ of the body. Upon looking at the patient's countenance again I detected a slight yellowish discoloration which, as in the former cases, suggested to my mind a favorable biliary origin of the colic. The tincture of dioscorea was then ordered, in 30-drop doses, with the gratifying result of yielding complete relief within six hours and enabling the patient to get up two days afterwards and attend to her household duties. The evacuations were carefully searched for a week but no gall-stones discovered.

### WHAT CAN WE DO TO INDUCE THE GOVERNMENT TO MAKE THE CEN- SUS OF 1890 CONTRIBUTE EFFI- CIENTLY TO A CLEAR CON- CEPTION OF THE CAUSES OF BLINDNESS.

*Read in the Section of Ophthalmology at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY ROBERT TILLEY, M.D.,  
OF CHICAGO, ILL.

The disinterested efforts which have been made by different individuals who have embraced the study of the healing art, for the general welfare of the race, will compare favorably with similar efforts made by any other section of the world's workers. Often these efforts have been made in the face of the wildest and most fanatical opposition, and practically always have they been confronted with appalling obstacles. It needs no mental acumen to perceive that in order to overcome successfully any evil we must know the nature of that evil, and according to our present experience we must know it in all its details. A disease which in some haphazard way disappears from our midst to-day will reappear at a place and time when we least anticipate it. But if we understand its peculiarities definitely we are not only in a position to try intelligently to suppress it, but also to try and abolish it entirely, or to successfully meet its future approaches. I am satisfied that if it were possible to get a complete

tabulation of the blind of the various countries of the globe a well-informed and well-balanced mind could draw very important deductions relative to many peculiarities of the various peoples. By a complete tabulation I mean a tabulation which should indicate not only the number of the blind, but also the various agents which have caused the blindness. One very peculiar and interesting fact has been strikingly illustrated by Dr. Hugo Magnus, of Breslau. Among the many interesting items in his excellent work, "*Die Blindheit ihre Entstehung und ihre Verhütung*," it appears that in Bavaria the census of 1840, 1858, and 1871, have shown that the Jews furnish a relatively greater number of blind than the Catholics, and that the Catholics furnish relatively a greater number of blind than the Protestants. He has further shown that the censuses of Prussia for 1871 and 1880 give corresponding results; namely, that in Prussia a given number of Jews furnish more blind persons than a corresponding number of Catholics, and a given number of Catholics furnish a greater number of blind than the same number of Protestants. I do not quote the actual figures presented by Magnus because my object is only to call attention to the item as one of interest in a census of the blind.

England and Scotland, in the census of 1871, furnish about the same relative number of blind, but a little in favor of Scotland. There can be little doubt that the relative number of Protestants is greater in Scotland than in England. Ireland, greatly in excess of England and Scotland, corresponds absolutely with the channel islands.

Comparing Ireland with itself, it is stated without further definiteness that the South of Ireland gives 17 blind in 10,000 inhabitants, whilst the North of Ireland furnishes only 9 in 10,000; not much more than one-half as many. The North of Ireland may in general be called Protestant.

If such figures as these are shown to exist throughout the various parts of the civilized world they certainly are of intense interest, whatever deduction we may draw from them.

Another item of interest which Magnus sets forth in detail in the book before referred to, is the number of blind from ophthalmia neonatorum. In a carefully prepared table giving the various causes of blindness in 2,528 cases examined by himself and other competent observers it appears that ophthalmia neonatorum contributed a larger percentage of blind than any other affection, namely, 10.87 per cent., and trachoma and blennorrhoea adultorum come next, with 9.49 per

cent. Without inquiring further these two affections thus contribute 20 per cent., at least, of the blind, and both of them must be practically considered as preventable diseases.

It is not improbable that these figures represent somewhat accurately the percentage which these affections contribute to the number of blind here in America. And when we remember that a case of blindness from ophthalmia neonatorum is a whole life-long affection, the seriousness of the affliction becomes apparent. According to the statistics of the lying-in establishments at Leipzig, which may be taken as a sample, in 1874 out of 100 infants 13.6 suffered from ophthalmia neonatorum, whilst in 1879 the proportion was 9.2 per cent. I remember, without being able now to cite the source, that a few years ago a report from one of the lying-in establishments in New York the proportion was about 10.7.

I have not at hand any definite and reliable figures showing the number of blind from this affection in the institutions for the blind in America. The principal reason why I have chosen to refer especially to this particular affection is because it affords an instance of the affection which of all others has been demonstrated to be the most favorably influenced by a system of prophylaxis. These prophylactic measures are well known to you and do not now concern me. What I desire to do is to induce you to make some effort to render the coming census of 1890 more complete relative to the general question of blindness. The importance of the question lies in the fact that it is only by an accurate estimation of the question that we can hope intelligently to modify its dire results. It ought to interest the moralist, it certainly must interest the political economist, the humanitarian and the physician. It certainly is not to the credit of any nation to have a relatively large number of blind among its citizens, and America ought to furnish a smaller number relative to her population than any other nation on the face of the earth. But it is useless to claim what ought to be, the only efficient means of estimation is to know what is, and the only means of intelligently profiting by the bare statement of the numerical fact is to know how it occurs.

I am aware that the tabulation of the blind with the various causes of blindness is a complicated and difficult question and that it cannot be accomplished by the general army which constitutes the census recorders. But that it is not impossible is shown by the efforts of some of the quiet workers of Germany—Katz, Magnus and Lackmann. That it is a work which cannot be accomplished by private individuals, and that it certainly would form a most valuable basis for a system of prophylaxis against blindness; that it would be a contribution to a kind of international hygienic and prophylactic exhibition; that it

[NOTE.—Were I trying to give an adequate conception of the disasters that arise from ophthalmia neonatorum it would be necessary to say that in twenty-two institutions for the education of the blind in different parts of the continent of Europe 40 per cent. of the inmates were blind from ophthalmia neonatorum.]

would furnish the physician, philanthropist, moralist and political economist facts relative to one of the world's greatest woes, should be stimulus enough to make the Government undertake the effort. Perhaps it is not to be expected that it could be satisfactorily carried out all over the United States at the first effort, but even if the effort was made in only a few populous and representative States, the interest and value of the work would be great. As has been previously stated, it is not for one moment supposed that the desired investigation could be accomplished by the ordinary census officers, all that could be expected from such officers would be a list of the names, ages, residences, nationality, religion, etc., of the persons afflicted, and the further work of technical classification of affections must necessarily be accomplished by men intimately acquainted with the nature of the diseases of the eye and ophthalmological phraseology. It would, moreover, be desirable that one recognized form should be used by all such tabulators. Magnus, of Breslau, has advocated just this work in his work referred to above, in reference to Germany; and to facilitate the matter he has drawn up a series of questions which leave very little, if anything, to be desired relative to simplicity, completeness and efficiency. I have translated this table without alteration, and will take the liberty to read it.

1. Name?
2. Age?
3. Religion?
4. Calling, before blindness; after blindness?
5. If a child, calling of father?
6. Parents related?
7. Parents' eyes affected?
8. Brothers or sisters affected with blindness?
9. Married?
10. Married before or after blindness occurred?
11. Husband or wife any affection of the eyes?
12. How many children with normal eyes?
13. Color of hair?
14. Color of the iris, when visible?
15. At what age did blindness occur in right eye?
16. At what age did blindness occur in left eye?
17. Condition of right eye?
18. Condition of left eye?
19. Cause of blindness in right eye?
20. Cause of blindness in left eye?
21. Grade of blindness in right eye?
  - (a) Total amaurosis?
  - (b) Quantative perception of light?
  - (c) Count fingers at 12 to 15 in. ( $\frac{1}{3}$  m.)?
22. Grade of blindness in left eye?
  - (a) Total amaurosis?
  - (b) Quantative perception of light?
  - (c) Count fingers at 12 to 15 in. ( $\frac{1}{3}$  m.)?
23. Was the blindness the result of a general affection?

24. Still affected?

25. Do any other conditions, important relative to the blindness, exist?

26. Did the blindness occur in the country or city?

27. How long a resident of the place before blindness occurred?

Such is the proposed list of questions which Dr. Magnus has formulated as a desirable list in order to give the investigation of the nature of blindness a uniform character. It would be difficult to modify the form in any scientific question without impairing its efficiency in some way.

It is not for us to suggest how such an investigation should be made. In order to be of value it should of course be accomplished within a short time of the general census returns; and if it could not be accomplished in all the States and Territories, it would be decidedly advantageous if it was done even but in a few States.

DR. J. L. THOMPSON, of Indianapolis, said: We should not be in too great haste in such a matter as this. Better by far teach the people, through the medical journals and newspapers, as to cleanliness and preventive treatment, than to resort to methods which, owing to the lack of time, gives to those whose duties concern the census taking have already been determined. Our country is vastly different from the older ones, being much more sparsely settled. Religion certainly has but little to do with the case. In the older countries in some quarters the Jews may have been more crowded, or possibly in the Catholic districts of Ireland and other countries the conditions of the people may not be as favorable as in other nations where the Protestants are often in affluent circumstances. Here eye diseases have been vastly increased since our internecine war, owing to the carelessness of returning soldiers communicating brachomatous inflammations to their families and friends by the use of the same towel, sleeping in the same bed, handling the same farming implements, etc. Educate the people, but let the Census Bureau alone. At least, as a Society, let us go slow about this matter.

Considerable discussion followed, in which Drs. Connor, Scott and Jackson took part. Finally it was moved and carried that a committee be appointed, by the Chair, to request the General Assembly to authorize the Section of Ophthalmology, together with the American Ophthalmological Association, to confer with the Census Committee. Drs. N. C. Scott, Robert Tilley and J. Chisholm were appointed on this Committee.

GEORGIA PHYSICIANS are agitating for an adjustment of fees. A meeting was held at Kingston to-day to advocate a universal fee bill.

## A NEW PLAN OF TREATMENT FOR PNEUMONIA.

*Read in the Section of the Practice of Medicine, Materia Medica and Physiology, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY G. R. MARTINE, M.D.,

GLEN'S FALLS, N. Y.

Every new theory is at first more or less ridiculed by the incredulous class, and the number of those incredulously inclined is unfortunately as large to-day as when Harvey discovered the circulation of the blood, or Jenner promulgated the boon of vaccination. Hence no surprise will be created should this new plan of treatment for pneumonia be derided, or even denounced in terms more vigorous than elegant. But still among you all there may be one patient investigator searching for truth, who will give this new theory a practical test; and if so, he will be induced to make a second trial; and when he ascertains that substantially it never fails, it will then become his fixed, permanent and unalterable practice in the treatment of pneumonia.

No attempt will be made in this paper to enter into an extended research or exhaustive analysis relative to the cause, pathology or results of pneumonia, or to discuss at length its different forms and phases. It is simply to a new plan of treatment toward which your attention is called, and to this point all efforts will be directed. Almost every known plan has been adopted in the treatment of pneumonia, and the new remedies have been eagerly sought after; first one and then another has played its rôle on pneumonia's stage with but indifferent success. Bleeding, vomiting, sweating, blistering, poulticing, depleting, stimulating, all local and all general plans of treatment have been faithfully and persistently carried out with marked thoroughness and perseverance; and yet to-day, after all the advancement made in the science of medicine, pneumonia, though a curable disease, stands second only on the roll-call of death. Shall we continue longer in these old ruts, with this appalling death-rate staring us in the face at every step, or shall we seek out a new and more rational plan of treatment?

The first abnormal symptom observed after the premonitory chill has warned us of pneumonia's approach, is the quickening of the pulse and the consequent increased flow of arterial blood. Now, if we could take a microscopic view of the minute arterial ramifications in the lung structure, we would discern in response to the law of causation, a distention of caliber in the arterial vessels in order to accommodate the augmented flow of arterial blood; and if we could then cast a glance at the veins, we would observe the plasma-layer rapidly filling with multitudinous white corpuscles, and the walls of the veins irritated by the friction of increased circulation would exhibit

here and there white corpuscles adhering to their tenacious sides, and finally penetrating their walls. A glance at the capillaries would show not only the white but also the red blood-corpuscles forcing their way through the overstrained capillary walls, until the surroundings became engorged by their extravasation, and the initiatory work of hepatization had commenced, for the comparatively large size of pulmonary capillaries, together with the fact of their not being supplied with vaso-motor nerves, render them easily dilatable under increased arterial pressure. Now what are we to do at this stage of the disease in order to hold in check this increased flow of blood to the lungs, which, if unrestrained, is sure to end in consolidation and death. Reducing the temperature will not accomplish the work. Reduction of temperature does not save in pneumonia as in idiopathic fevers. To what plan, then, shall we resort in this exciting emergency to save the patient from being suffocated by his own blood? Before an answer is given, allow me to use a simile: Should some mischievous hand hoist the gate of an immense reservoir, located at an elevation a thousand feet above this city, and the maddened waters, fiendish with the power of inundation, should sweep through your streets, undermining block after block, and strangling all life within reach of its destructive course, would you not intuitively cry out, shut down the head-gate and save the city?

When the maddened blood, fired by the lash of inflammation, rushes wildly through the channels of life, extruding with demoniacal force through the very walls of the blood vessels the blood-corpuscles and threatening to strangle out the life of the unfortunate victim, intuitively I cry out, shut down not the head-gate but the heart-gate and thus save the suffocating patient who helplessly looks to you for rescue. Say to the wildly pulsating heart, so far or so fast shalt thou go, and no faster, and continue to hold the heart's action under absolute subjection until the crisis is past and the life of the patient is saved. (This crisis is usually reached about the seventh day after the chill.) This is not only what should be done, but what *must* be done, in order to ward off death. Here is where the new plan saves life. You will naturally ask if this new plan is intricate or difficult of adoption, or if it be so extended or complicated as to render it practically inoperative in the hands of the busy practitioner. The answer is, no. The whole method can be given in five words, viz: Hold the pulse below eighty. Keep your fever thermometer in your pocket; it is of little or no use in pneumonia. Death does not result from high temperature in pneumonia, but from high arterial action, resulting extravasation and consolidation and consequent heart failure. The physician who, dallying with his fever thermometer, endeavors to cure

pneumonia by reduction of temperature, will make about as much headway and will be about as successful as he would in trying to eat soup with a peg-awl. You may ask with what remedies do you hold the pulse at this point. While *veratrum viride* seems to have served me best, possibly there are other arterial sedatives which in the hands of others may act as well. It has heretofore been the practice of medical writers to name the medicines to be used in the treatment of such and such diseases, but in the light of the present day it would be well to drop this antiquated custom and adopt a new method by stating the indications to be fulfilled, the dangers to be avoided, the vantage ground to be gained, the favorable signs to be sought for, and the unfavorable symptoms to be controlled, the main points to be attained, and the results to be expected in the successful management and treatment of any disease, and then allow the attending physician to select such remedial agents as he may choose from among those possessing his confidence after long experience in their use.

In pursuance of this course no radical line is drawn or arbitrary rule laid down as to the remedial agents used, provided they are successful in accomplishing the work of holding the pulse below eighty if in adults, or if children, from one hundred to one hundred and twenty. This point attained and with persistent vigilance maintained, no further trouble need be apprehended, for with the pulse at or below eighty, there will be no extravasation, if no extravasation there will be no consolidation, if no consolidation there will be no hepatization, and if no hepatization there can be no suppuration, mortification or death. Hence pneumonia, by this plan, can be robbed of all its terrors.

But the inquiry may be made: What is there in this plan to provide against heart failure, a condition so greatly to be dreaded, and the reply is: It is far better to *avert* a calamity than to *provide for* one. No censure is due the captain of a man-of-war who thickly covers his deck with sawdust to prevent slipping when blood shall flow freely; but a higher meed of praise is accorded that captain who so carefully erects defenses, so skillfully plans the attack, so closely watches the progress of the battle, and so adroitly conducts the fight that but little blood need flow.

So in this new plan of treatment for pneumonia, but little blood will flow if the pulse be kept below eighty. If no blood be extravasated no consolidation takes place, and if no obstruction from consolidation exist, and the heart's muscular labor be not consequently increased by its continued efforts to force the blood through pulmonary channels already clogged and blocked, and provided further that the heart is restrained and thus relieved from the fatiguing additional labor of 2,000 to 4,000 contractions per hour

during the seven days preceding pneumonia's crisis, heart failure in uncomplicated pneumonia would be a thing impossible.

DR. H. A. HARE said that the use of *veratrum viride* was old and very useful, but that a great mistake is made in saying "use cardiac sedatives in pneumonia" without recognizing the fact that they are to be used in the first stage before congestion has gone on to consolidation. The man who gives such drugs at the middle or end of an attack of pneumonia might as well stab his patient. *Digitalis* is to be used at such times. As to the lethal results of *veratrum viride* let me say that very few cases of death are on record, owing to the vomiting which is brought on very early by the alkaloid *veratroidia* and an emetic resin. It is certainly the safest cardiac sedative.

DR. I. E. ATKINSON, of Baltimore, objected to the claim that the use of *veratrum viride* in the treatment was new; it had been many years under trial and had not received general acceptance. He called attention to the fact that Dr. Martine's graphic description of "drowning in their own blood" as the mode of death in many cases of croupous pneumonia could not be justified; that frequently the cause of death was in the failing heart action, a condition to which we could not look for benefits from heart depressants. He would not be much impressed by the successful results of giving *veratrum viride* in the croupous pneumonia of children, since this disorder usually will recover under any ordinary treatment.

DR. CRONYN said: Dr. Martine's new mode of curing pneumonia is not at all new. Bleeding and rasher emetics were the methods of our forefathers to attain the results pointed out by the doctor. We know very well that about forty years ago a complete revolution in the treatment of diseases generally, and pneumonia, was made the basis of argument particularly. I hold, sir, that every case of inflammation of the lungs must be treated upon its own merits, taking into consideration the constitutional condition. The peculiarities of such cases and the remedies are easily determined.

DR. C. O. PROBST, secretary of the Ohio State Board of Health, is sending out circulars to the mayors and councils of all the cities of that State that have not formed boards of health, urging them to do so. The law requires all towns having a population of five hundred or more to establish these boards. The circular says: "One of our smaller villages, which neglected its duty in this matter, is now paying the penalty in a severe epidemic which a board of health might have prevented."—*Sanitary News*, Sept. 7, 1889.

## MEDICAL PROGRESS.

**ACQUIRED LEPROSY, AS OBSERVED IN ENGLAND.**—MR. JONATHAN HUTCHINSON believes that while the possibility of contagion in leprosy is universally admitted in what may be called the abstract, it is very doubtful whether it takes an important share in the spread of the disease; thus, lupus and cancer might be transferred from one person to another, but neither is contagious in a practical sense. In Norway, India and the West Indies nurses and surgeons do not fear to come into contact with lepers for years together. So far as *contagion* is concerned, hundreds of surgeons daily encounter the same risks that Father Damien did, but the latter exposed himself to other dangers as well—to those of food, for example. In England the most intimate possible contact with lepers has not been sufficient in itself to communicate the disease. The varieties of leprosy are the same the world over, in hot and cold countries alike, facts pointing to the inference that the cause must always be the same. In countries where leprosy has died out it has died out absolutely—not a single sporadic case ever originates in England. The cause for the spread of the disease must be sought in *food*; there is little room for doubt that it depends upon some very special kind of poison taken in connection with food. Such an hypothesis would cover all the facts, and none other would.

In connection with his opinions Mr. Hutchinson cites twelve cases which have come under his observation. These were all in patients of British birth. There was no inherited predisposition. In no instance had the patient been exposed to any degree of hardship or deviated from the ordinary conditions of well regulated life. In every case the acquisition of the disease had occurred in some country where it was prevalent. The patients must have received the specific contagion on some part of the skin or mucous membrane, or must have swallowed it in connection with food. All had, however, partaken of food common in leprosy districts, and if we incline to suspect that fish, and especially potted fish, is an ordinary vehicle of contagion, all had undoubtedly been exposed to this risk.—*Brit. Med. Journal*, Nos. 1,487 and 1,488, 1889.

**THERAPEUTIC VALUE OF HYPNOTISM.**—(From a paper read by M. BERNHEIM before the International Congress for Hypnotism, Paris, August, 1889.) The hypnotic state is that particular psychological state which may be produced and which increases, in varying degree, suggestibility—that is to say, the aptitude of being influenced by an idea that the brain receives and realizes. This is a definition more comprehensible than that generally employed, for to define hypnotism as an

induced sleep is to eliminate from hypnotism a class of cases with great tendencies toward suggestion and even hallucination, for there may be hypnotism without sleep.

I obtain some remarkable effects without sleep. I request the patient to close his eyes; I seek to make an impression on him—to make his mind captive, and I affirm the disappearance of certain functional troubles. This is suggestion by word without hypnotism. Sometimes the suppression of a functional trouble or an acute pain may be accomplished instantaneously either permanently or temporarily; at other times it is only gradually brought about at the end of a number of *séances* depending upon the nature of the trouble and the degree or character of the suggestibility. Hypnotism does not enjoy a monopoly in *suggestion*; the latter may be produced by other means, it has been practiced in all times by physicians with better or worse intent. Purgation by pills of bread-crumbs, the cure of fits by fear of the police, sleep induced by the peroxide of hydrogen, the miraculous water of Lourdes, the practices of the touchers and the masseurs, those of hydrotherapy, metallothrapy, electrotherapy, the secret ointments, the granules of Mathei, homeopathy and the suspension treatment of patients with tabes, all act in part or whole through suggestion. Doubtless hydrotherapy and electrotherapy have of themselves an incontestable action upon the functions of the organism, but this action is not well understood; the assertions of the authors regarding the therapeutical value of the various methods are vague and contradictory for the reason that no one has taken pains to first disengage the element of suggestion.

I often have success with the use of electricity in the treatment of neuralgias, rheumatism, lumbago, nervous aphonia, etc., when I fix my patient's attention closely upon the effects obtained under electrization and tell him that his symptoms will disappear. Electrization with suggestion sometimes succeeds where suggestion alone fails. One of my patients had suffered for months from extremely severe lumbar and sciatic pains. Electrization with suggestion (the vigil state) caused disappearance of the pain at each *séance*, but only for a few hours. I then tried hypnotic suggestion, but with less effect. The patient expressed more confidence in electrization and said that hypnotism alone had no effect upon him. I returned to my former treatment with the result of obtaining a complete cure in two or three weeks.

In metallothrapy I have been able to discover nothing of value aside from the element of suggestion; I do not deny that it possesses other powers, but I have been unable to discover them. I have often applied various metals and magnets to the anæsthetic skin of hysterical patients without informing them of what I was doing, and without producing any effect. By applying the

metal, however, and saying to the patient or the assistants, "here is the metal or magnet which I wish to apply; in three minutes sensibility will return in the hand and in half of the forearm," I often obtain the desired result. The English seem to me to be right (at least in part) when they ascribe the therapeutical action to expectation. The treatment of tabes by suspension has made a great deal of noise lately. The surprising benefits obtained have been attributed to the changes produced in the blood-supply of the spinal marrow, as well as to the stretching of the nerves. From the very first I have thought that suspension is a method of suggestion. Numerous experiments of this sort, by myself and as well as others, upon patients suffering from ataxia and other varieties of myelitis, nocturnal incontinence of urine, and especially the various forms of neurosis, have led them to the same conclusion. The science of medicine endeavors to explain all the mysteries of life by mechanics, physics, and animal chemistry, but the mind is also a factor in the human organism; there is a psycho-biology and a psycho-therapy.

My final conclusion is that suggestive therapeutics rests upon the incontestible influence exerted by the mind upon the body. Its influence upon digestion, nutrition, respiration, circulation, and upon the secretory or excretory functions, is well known, for all the organs, all the functions are in anatomical and physiological relation with the cerebro-spinal nerve centres. Every cerebral cell influenced by an idea tends to realize this idea through the agency of the nerve fibres. The idea becomes an act. Upon this physiological fact is based the psycho-therapeutics of suggestion.

The hypnotic state itself produced by suggestion increases suggestibility by suppressing intellect and augmenting cerebral automatism. It is faith that saves, and the most incredulous people have a faith (I do not say a religious faith); they are no more able to escape from it than they are able to escape from the hallucinations of their dreams. Credence (I do not say credulity) is inherent in the human mind, and thus it is that the human mind becomes a master workman in miracles.—*Le Bulletin Médical*.

**THE PROPHYLAXIS OF TUBERCULOSIS.**—Last year a congress for the study of tuberculosis was held in Paris. At this meeting a permanent committee was appointed to formulate simple and practical instructions regarding the prophylaxis of tuberculosis. On behalf of this committee M. VILLEMEN has recently submitted a report which had already been approved by four professors of the medical faculty of Paris. The following is a brief summary of this report:

1. Tuberculosis is, of all diseases, the one which has the largest number of victims in the

cities, and even in certain country districts. In 1884, for instance, of 57,970 deaths in Paris, 15,000 were due to tuberculosis.

2. Tuberculosis is a virulent contagious transmissible parasitic disease produced by a microbe, the bacillus of Koch. This microbe, apart from direct hereditary transmission, finds its way into the organism through the digestive and respiratory tracts, and through wounds of the skin and mucous membranes. The propagation of tuberculosis may be prevented by well directed precautions.

3. The parasite of tuberculosis may be found in the milk, muscles and blood of the food animals. The use of raw and underdone meat and blood that may possibly contain the living germ of tuberculosis should be prohibited. Milk, for the same reasons, should be boiled before being used.

4. On account of the dangers concealed in milk the protection of infants, who are so easily attacked by tuberculosis, should attract the special attention of mothers and nurses. The tuberculous mother should not nurse her child. Cow's milk, when given, should always be boiled. There is less danger in giving ass's and goat's milk unboiled.

5. It is greatly to the interest of the public to assure the proper inspection of meat, as provided for by law. The only sure way to avoid the dangers of tubercular meat is to see that it is *thoroughly* cooked.

6. Inasmuch as the germ of tuberculosis may be conveyed from a tubercular to a healthy man by the sputum pus, inspissated mucus, and any object containing tubercular dust, it is necessary to bear in mind that:

1. The sputum of phthisical persons being the most dangerous agent of transmission, there is a public danger from its presence upon the ground, carpet, hangings, curtains, napkins, handkerchiefs, cloths and bedding.

2. The use of cuspidors by everyone should be insisted upon in all places. Cuspidors should always be emptied into the fire and cleansed by boiling water. They should never be emptied into rubbish piles, upon gardens, or where there is a possibility of infecting poultry, or even into water closets.

3. It is unsafe to sleep in the bed of a tuberculous patient, or to spend a great amount of time in the room of such a patient; least of all should young children be allowed to sleep in such a room.

4. Individuals considered as predisposed to contract tuberculosis should be kept away from localities frequented by phthisical patients.

5. One should not use objects contaminated by phthisis (linen, bedding, clothing, toilet articles, jewelry, hangings, furniture, playthings, etc.), except after suitable disinfection.

6. Rooms and houses occupied at watering places and resorts should be furnished in such manner that disinfection may be easily carried out after the departure of each invalid. It is the best plan of all to furnish rooms without curtains, carpets or hangings, to whitewash the walls, and cover the floor with linoleum.—*Bulletin de l'Académie de Médecine*, July 30, 1889.

**IMMEDIATE TREATMENT WITH CURE OF LACERATIONS OF THE CERVIX UTERI.** By MARY E. BATES, M. D.—The writer believes that there are insurmountable objections to suturing a lacerated cervix within a few hours of the termination of labor; first, because of the condition of the patient and of the wound; second, because of the difficulty of introducing the sutures; third, because of the dangers incident to the necessary exposure, and finally because of the impossibility of accurately determining the extent of the laceration. Operations made three or four months *post partum* present certain advantages which are not possessed by the late operations.

A few lacerations may heal by first intention without any special interference, though in the majority of cases involution and repair will not take place satisfactorily. In lacerated cervix the indications are to promote involution and repair:

1. By stimulating the pelvic circulation.
2. By cleansing the parts.
3. By keeping the edges of the wound in apposition.
4. By relieving the relaxed ligaments by supporting the uterus.

These desiderata may be secured by tamponing the vagina with antiseptic wool. This is to be introduced in such a manner as to keep the edges of the wound in close contact and give support to the uterus. The tampon may be left *in situ* for two or three days at a time, and should be reapplied two or three times. After the patient gets up the uterus should still be supported by tampons for at least two weeks longer. By these measures excellent union can be obtained and the processes of involutions be materially hastened.—*Southern California Practitioner*, July, 1889.

**FRACTURED STERNUM WITH DOUBLE PLEURO-PNEUMONIA.**—A man, 64 years of age, was admitted to the General Hospital, Birmingham, in the service of SIR WALTER FOSTER, on May 20th. Respirations were 58, temperature  $103^{\circ}$ ; there was urgent dyspnoea and pains in both sides of the chest. An examination revealed a double-sided pleuropneumonia. There was dullness at the lower part of the chest and at the sides, together with bronchial breathing, crepitation, violent cough and thick tenacious expectoration. The lower part of the sternum from the upper border of the fourth costal cartilage moved with

each respiration, giving distinct crepitation. The patient had sustained a severe fall four days previously. Treatment consisted in strapping and the administration of stimulants and a mixture containing acetate and carbonate of ammonia and squill. By the eighth day the respirations had dropped to 44. On the 16th there was a fresh extension of the pneumonia at the left base. This attack passed off, and on the 21st he was free from pain. From this date he made a good recovery, and was discharged on July 11th, at which time the chest-walls moved fairly, the respiratory sounds at the bases were good, though accompanied occasionally by dry, creaking sounds. Union of the sternum had taken place.—*British Medical Journal*, Aug. 3, 1889.

**TUBERCULAR MENINGITIS IN THE ADULT.**—A man of 52 years, while apparently in the midst of health, had a profuse pulmonary hæmorrhage, followed by consolidation of apex of left lung, in 1887. Milk diet and creosote medicinally for eighteen months enabled him to gain markedly. Temperature during this time, about  $99\frac{1}{2}^{\circ}$ ; expectoration scanty; increase in weight, 40 pounds. There was a recurrence of the hæmorrhage in July, followed by rapid formation of cavity at apex of left lung and profuse expectoration of pus. He rallied and resumed work after an interval. In March he suffered greatly from headache, with exacerbations on alternate days. Temperature,  $105\frac{3}{4}^{\circ}$ . Nothing served to relieve pain or reduce temperature. After six days delirium set in at intervals. The respiration took on the character of the Cheyne-Stokes type, which continued until death, except as modified by the administration of atropia and strychnia. Convulsions and death eighteen days after the appearance of cerebral symptoms.—*N. O. Med. and Surg. Journal*.

**THE PATHOGENY OF NEPHRITIS BY SELF-INTOXICATION.**—E. GAUCHER reports, in the *Revue de Méd.*, No. 11, 1888, experiments made on guinea-pigs with leucin, tyrosin, kreatin, kreatinin, xanthin, and hypoxanthin. Subcutaneous injection of these substances produced (like mineral substances: mercury, phosphorus, arsenic, etc.; and vegetable substances: oxalic acid and fuchsin, as proven before by the same author) in every case a nephritis of the epithelium which led to granular fatty degeneration especially of the epithelium in the tubuli contorti. The author warns against giving food rich in extractives (bouillon, meat-extracts, meat-powders, etc.) in all cases where with a disturbed digestion the transformation of azotic nutriment occurs imperfectly, as a nephritis threatens from overburdening the organism with such extractives.—*Centr. für Klinische Medizin*, No. 23, 1889.

SATURDAY, SEPTEMBER 21, 1889.

EXTRACTION OF CATARACT WITHOUT  
IRIDECTOMY.

A careful perusal of the comparatively short but eventful history of cataract extraction, will not only repay the reader for his trouble, on account of the interest inherent to the subject, but will also put him in possession of certain facts regarding this operation which will prove of special interest at the present moment, when the question of modifying the usual method of operating is agitating the minds of ophthalmologists.

The history of an operation is the record of men's experience therewith. Therefore when the surgeon is invited to set aside an operative procedure by which he obtains good results, and to adopt a modification of a once discarded operation, it behooves him to turn to the pages of its history, so that he may profit by the accumulated experience of others. The record should be carefully reviewed and the reasons for its having been discarded thoroughly studied. The causes of failure in the past should be examined in the light of our present knowledge, and whether any discovery has been made by which the obstacles to success can be surmounted, is not only a most pertinent question, but one which demands a satisfactory answer.

If the annals of ophthalmic surgery are consulted it will be found that up to the middle of this century the operation for cataract most generally performed was the classical "flap extraction," without iridectomy. It is undeniable that when this operation was entirely successful the result was in every respect all that could be de-

sired. The corneal scar was hardly perceptible, the iris retained its normal form, and the patient, once being rid of his opaque lens, looked through a round and movable pupil. Nothing more could possibly be demanded of ophthalmic surgery. Unfortunately the number of perfect results fell far short of what was desirable. The large corneal flap was apt to suppurate, leading to the total destruction of the eye. The iris, which was oftentimes badly bruised during the expulsion of the lens, frequently reacted, giving rise to harassing iritis, and entailing the contraction of the pupil, with loss of motility and of its regular form. But the great disadvantage of the procedure was the danger of prolapse of the iris. In many instances the result of a perfectly smooth operation, giving promise of a brilliant outlook, was marred by a prolapse of the iris supervening, perhaps, two or three days after the operation, from a fit of coughing, or some other effort, and sometimes without any apparent cause. In some instances the performance of an iridectomy succeeded in setting free the entangled iris, but in the majority of cases the patient was sent out carrying in his eye a source of irritation which constantly menaced the integrity of the organ.

To obviate these difficulties Gibson and Travers, in the early part of this century, tried to extract certain forms of cataract through a small linear incision; Bowman and von Graefe, simultaneously, although independently, revised this method toward the middle of this century, adding one more step to the operation—the removal of a small portion of the iris. Finally, the mastermind of Graefe, perceiving that each operation offered certain advantages, and that neither was adapted to all cases, devised, and then gave to the world, the "modified linear extraction," which did away with the disadvantages of the old flap and the linear extraction, and combined the advantages of both.

The result was most satisfactory along the whole line of operators. Even those who had performed for many years the old flap extraction, securing its occasional brilliant results, reluctantly gave way before the obvious advantages of the new operation, and went over to the ranks of its advocates. The reason for this unconditional surrender is not to be sought, however, in any alleged perfection of the method, for its subsequent history revealed that the operator had to

encounter other dangers, such as the escape of vitreous when the incision was made too far into the sclerotic; but the reason for its general adoption is to be found in the fact that it eliminated almost entirely the two prevailing sources of failure in the old operation, viz.: suppuration of the cornea and prolapse of the iris.

The operation was not destined to live long in its original form. Notwithstanding the acknowledged advantages ensured by the iridectomy, the eyes of some ophthalmologists turned back with longing toward those round, movable pupils obtained in the good old days of flap extraction. Soon the incision began to travel more into the cornea, and every effort was made to do away with the defacing iridectomy. Modification followed modification in rapid succession, so that after a few years all that remained of Graefe's original operation was the knife. Finally a calm ensued, during which the merits of all these modifications were thoroughly tested. The majority of ophthalmologists, perceiving that Graefe's claims were satisfactorily sustained by experience, gradually settled down to perform extraction with iridectomy, limiting their modifications to slight deviations from the original form and seat of the incision. A few operators, however, have from time to time made desultory efforts to banish iridectomy, but within the last two or three years there has been a well-defined movement in this direction. The proposed operation is known as "simple extraction."

As this movement is led by some of the most distinguished ophthalmologists in Europe and America it is bound to command attention, and to exert great influence. Furthermore, some of its advocates are most enthusiastic, and their claims are in some instances supported by carefully prepared reports. To gainsay the statements made by such men is, in a sense, to stand condemned in one's own words. Yet it is unquestionably true that a calm, dispassionate examination of the merits of simple extraction, which, after all, is but a modification of the old flap operation, does not reverse the verdict of the past. It is quite true, that the advances made in antiseptic measures have greatly diminished the dangers of suppuration of the wound, but the proposed improvement over the "combined operation," does not depend so much on the form of the incision, as it does upon the banishment of

the iridectomy. And in this particular no advance has been made which will help us out of the old difficulty. The surgeon's control over an eye ceases when the bandage is applied, and the worst cases of prolapse occur after this time. It has been suggested to leave the bandage undisturbed for six days, and to restrain the patients more to their beds, but notwithstanding all these precautions the dreaded "*bête noire*," as Critchett used to name prolapse, will occur, and an anterior synechia is universally recognized as a most undesirable complication.

That removal of lens without performing iridectomy (thus securing a round, movable pupil) is the goal to which every experienced oculist should direct his steps, is undeniable. But the road to this goal is full of pitfalls and difficulties. Hence a note of warning should be sounded for those who have not acquired sufficient experience in ophthalmic surgery to realize the dangers which lie ahead. It requires a most experienced eye to discover when a lens can be extracted without iridectomy, and further, it necessitates a nicety of manipulation acquired only by years of practice to thus accomplish its removal. Let simple extraction then take its place as the ideal operation, but let us bear in mind that like many other ideals it is not always practicable. The modified linear operation, as performed to-day, offers inducements, both in safety of procedure and in brilliancy of results, which cannot be denied, and which should not be underestimated.

Many distinguished ophthalmologists who had discarded iridectomy have returned to it, experience having taught them that it is safer in the long run. It therefore behooves the *expert* operator to weigh the evidence most carefully—the *beginner* should unquestionably adopt the method which on the whole offers the best assurance of success.

LEPROSY IN NOVA SCOTIA AND NEW BRUNSWICK.—Dr. Smith, the medical attendant of the Tracadie Leper Hospital, New Brunswick, having been commissioned by the Canadian Agricultural Department to make inquiry concerning suspected cases of leprosy reported in Nova Scotia, fully confirms the diagnosis. It is also reported that there are a considerable number of other cases believed to exist in the northern part of the province.—*Brit. Med. Journal*.

# AUTO-INFECTION FROM THE PRODUCTS OF GASTRO-INTESTINAL FERMENTATION.

There is a large and important class of cases, examples of which are constantly coming under the observation of the general practitioner, sometimes under one guise, sometimes under another; at times bearing clinical aspects of familiar appearance, again presenting an array of symptoms without apparent interdependence and exhibiting manifold functional disorders which seem to affect every organ of the human economy, and to spring from sources so well hidden as to baffle the quest of even the astute physician. These are the cases of that hydra-headed enemy of modern civilization, INDIGESTION. To compass etiology we are obliged to summon to our aid all the wisdom of physiology, chemistry and bacteriology. In our efforts at treatment we have already well-nigh exhausted the resources of materia medica and dietetics, and have little to fall back upon save hygiene—*id est*, common sense.

We can scarcely doubt—indeed, we have already admitted—that it is the Americans who have received the worst drubbing from this monster; and yet, at first blush, it would seem as though the United States, the granary and pasture of the world, with a population supplied with a greater variety and better quality of food than any other nation, would hardly be this monster's favorite victim. It might be said, indeed, that we have too great an abundance, and that we are suffering from the results of too much luxury and refinement in eating and drinking. But if sophistication in the preparation of food is a danger, it would seem that the French, with their culinary subtleties; the Germans, with their insipid steamed meat and stomach-destroying "*mehlspeisen*," and the Italians, with their garlic and oil, ought all to come in for their full share of punishment. The truth of the matter is, doubtless, this: The Americans are no more indiscreet in what they eat and drink than are the other nations. The difference is rather to be found in the *way* they eat and drink, and in the manner of their life; in other words, the hygiene of European life is, in many respects, more rational than ours. In European life there is less hurry, less anxiety, less precipitation, and more of out-door life and physical exercise. Even their habits of drinking are less injurious than ours, for they rarely drink beer or wine or liquor

except at meal times. In fact, were it not for the abhorrence that the continentals exhibit for fresh air within doors, one might say that nearly all their hygienics are superior to our own.

Fortunately enough for the great army of "dyspeptics," the work that has been done in the study of the causes and treatment of the disorders under consideration (and certainly in no department of medicine has more been done than in this) has borne rich fruits; and especially may we congratulate ourselves in the development of the facts elicited by the aid of bacteriology. From the chaos of dyspeptic symptoms we have learned to differentiate, more or less accurately, certain complex uses of disordered function which supply us at once with the keynote of etiology and the guide-post to rational treatment. The modest general practitioner, who has hitherto feared lest he might tread upon the toes of the redoubtable neurologist, is beginning to learn that it is really the latter who has all along been trenching upon the general practitioner's own favorite field. Auto-infection has now come to explain to the general physician much that has hitherto been a perplexing puzzle to him. Brunton has drawn attention to this matter in the following striking expressions: "Perhaps we are not yet sufficiently alive to the important results produced by the absorption from the intestinal canal of substances generated in it by fermentation, or imperfect digestion. We recognize the danger of breathing gas from a sewer, but probably we do not sufficiently realize that noxious gases may be produced in the intestines, and, being absorbed into the circulation, may produce symptoms of poisoning."

An excellent illustration of this thought is found in a recent contribution to the *New York Medical Journal* on "Nervous Symptoms Caused by Functional Gastro-intestinal Disorders," by Drs. W. W. VAN VALZAH and CHAS. R. CRANDALL. To a very interesting report of such a case these writers have added an able analysis of the underlying causes, together with the rational indications for treatment in this and similar cases. The patient in question was a typical one of a class, a middle-aged American gentleman, a lawyer by profession, and a member of Congress. Of neurotic ancestry and of nervous temperament, the excitement and strain of such a career as he chose, and a moderate disregard of the ordinary

laws of hygiene, was all he needed to become what he was—a constant sufferer, tormented by a great variety of aches and pains. Even in boyhood and early manhood he was a martyr to indigestion, as well as the victim of numerous acute diseases. In the full tide of his activity his business affairs were interrupted by frequent breakdowns, requiring him to discontinue work and resort to watering places and take extended journeys in the interest of his health. He suffered greatly from insomnia, nervous irritability, inability to concentrate his thoughts, pain and burning sensations in his limbs, distress after taking food, acidity, flatulence, grinding sensations in the stomach and bowels, constipation, etc. A physical examination also revealed a gaseous distension of the stomach and intestines, the presence of yeast ferments in the blood, and of phosphates and bile in the urine, which showed a specific gravity of 1.030. The treatment instituted and faithfully carried out consisted almost entirely in altering the hygienic conditions of this man's life. He was placed in the midst of healthful mental and moral surroundings. To these were added rest, freedom from all sources of irritation, baths, massage, moderate exercise, and a suitable diet, which consisted in the withdrawal of fermentable food, including all sweet, starchy and greasy articles, all fruits and vegetables, and everything containing acids. His diet was almost entirely one of animal food, composed mostly of beefsteak and the muscle pulp of beef prepared by a machine made for the purpose. Meanwhile frequent examinations were made of the patient's blood, urine and feces. Later on, when a less restricted diet was enjoined, he was allowed to gradually add stale bread, a small quantity of milk, then a little game, and finally some vegetables. Tea, coffee and stimulants were all prohibited, and he was required to drink a pint of hot water one hour before each meal. As regarded the use of purely medicinal agents, such were administered as tended to give tone to the nervous system, stimulate the digestive organs to better action, aid the digestion of food, and induce rest to the nervous system. The particular ones chosen were cinchona, nux vomica, damiana, salicin, cascara, pepsin, bromides, and sulphonal. Under this treatment, in a single month, the patient passed from constant wretchedness to a state of entire comfort. After three

months of such treatment he returned home, not cured, indeed, but on the high road to health.

It is by such thorough examinations of our patient's condition, and by such rational application of the simple remedies which, when judiciously employed, possess so great a potentiality for good, that we may hope to obtain success in the treatment of digestive disorders when once they become fairly established. But in this, as in most other diseases, the best of all treatment is the prophylaxis, and here it is the wives and daughters who are the real physicians; and it is our firm belief that until the domestic arts of the kitchen and dining-room attain a rank of dignity among the other accomplishments, until they are taught very much as music and painting are taught, it is going to fare pretty badly with all of us.

---

#### THE PHYSICIAN AND HIS JOURNALS.

There is an ever present tendency among men, in a sort of vague and misty way, to venerate the past; in a way quite egotistical to magnify the present, and also to compass the future with grandiloquent interrogations.

To the first and third counts we plead not guilty—but to the second we enter our confession, since a simple statement of facts can hardly seem to those in other lands other than most notable exhibitions of egotism. When we come to enumerate the medical practitioners in the United States, the number of our medical schools and their improved facilities for teaching, the rapid development of medical societies and the numbers of medical journals that are in demand, we submit that the parallel is not to be found in the past or present history of any nation. If any one has doubts upon this subject we commend to him the simple study of statistics. Again, there never was a time when in this and in other lands there was such an array of talent applied with utmost tension, to medical investigation. There was never a time when there was so much of original discovery, and never before such facilities for rapid advances in medical education. There never was a time when medical journalism was so enterprising as now, nor its pages so filled with valuable instruction, and there never was a time when a physician could so soon fall behind and be lost sight of as now. A single year's neglect will

render his needs conspicuous. Only the most industrious and critical readers are fully abreast of the times, and in the hour of need and of their opportunity how quickly these come to commanding prominence.

If all these facts be true, how can we do otherwise than by their simple statement magnify the present? If they be true it is obvious that to the well informed physician his journals are as essential as is his daily bread. And while making his selections, will he pardon if we make one or two suggestions.

We believe that a first duty of the medical man is to help develop, foster and sustain the medical societies and medical interest of his own locality. He has power personally to stimulate his associates and to aid them in organization and in medical progress. In the development of such local interests nothing can be so helpful as the ably conducted and well supported local medical journal. To this he owes a primary obligation, both literary and pecuniary. Its pages should be replete with the recorded experiences of local contributors while, in turn, it should garner for them the best of medical productions from all lands.

To the physician in quest of his second journal we respectfully commend the value and the claims of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. While it is National in its relations and circulation, it will seek to further his local interests. It will give a continued series of valuable original papers, prepared and submitted by the leading men of the profession, at the annual meetings of the American Medical Association. It will give prominence to translations of the best literature published in foreign languages, and copious selections from the best writings at home and abroad. It will devote itself to the dissemination of clinical instruction, and to the presentation of condensed reports of the proceedings of prominent medical societies. These, with the work of a corps of editorial writers widely representative of the American States, constitute our claim to the second place on the physician's list of medical journals, to which he should add as many others, home and foreign, as he can *thoroughly utilize*.

**BUTCHER-SHOP REGULATION.**—The Municipal Council of Paris has ordered that the débris of butcher-shops shall be removed before daybreak.

#### THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

The fifteenth annual meeting of this Association was held in the city of Evansville, Ind., September 10, 11 and 12. The Committee of Arrangements had made ample provisions for every need and their work seemed perfect in every detail.

The meeting was one well representing the leading men of the Mississippi Valley and was conspicuous, *first*, for the absence of any excessive convivial spirit; and *secondly*, for the earnest purpose with which, from first to last, the members applied themselves to solid scientific work. Of the eighty-three papers which had been prepared for this meeting seventy-one of the writers were at hand to present them in person. Owing to the admirable tact of the presiding officer not a moment was lost. The papers followed in quick succession. The discussions which they elicited were as conspicuous for their aptness and force as were the papers themselves.

It may seem to the members of our Association in other portions of this broad land that THE JOURNAL is according undue prominence to this particular organization; in answer to which we wish simply to say, that wherever, or whenever an association shall so manifest its interest in, and its loyalty to, the American Medical Association as does this, and command within itself such elements of strength and culture, THE JOURNAL will be only too glad to recognize its claims and, as in this instance, to further its interests in every possible way.

Our regret is, that in connection with the publication of Association papers the pressure upon our columns will not permit the solicitation of a number of those there presented, for a like purpose. Our cotemporary journals, it is hoped, will afford ample and adequate facilities for their dissemination. In the present issue we give, as fully as our space will permit, an outline Report of the Proceedings.

---

#### EDITORIAL NOTES.

##### HOME.

**THE DELAWARE HOSPITAL.**—The corner stone of this hospital was laid by the Masonic Grand Lodge on the 17th ult. Dr. L. P. Bush, President of the Hospital Board, in his address said that "had the desire of the physicians of Wil-

ington been carried out there would have been a place long ago to which the sick and wounded of our city who were in need of assistance could be taken. But it is a happy event which has brought us here to-day to attempt to supply the deficiencies of the past and to help to wipe away whatever of odium may have rested upon the reputation of our city by this neglect."

The building will be ready for occupation before the close of the year. The present structure will be added to from time to time. A copy of THE JOURNAL, together with a copy of each of the local papers, the New York *Herald* and Philadelphia *Press*, were placed in the foundation stone.

NEW YORK MEDICO-LEGAL SOCIETY.—At a meeting of this Society held at the Hotel Buckingham last Wednesday the following papers were read: "The Hygiene of Interments," by Dr. C. A. F. Lindorme, of Florida; "Classification of the Varieties of Insanity," by Dr. Joseph Jones, of New Orleans, La.; "Résumé of Recent Trip to Europe," by Clark Bell, Esq.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its next session at Nashville, Tenn., November 12, 13 and 14, 1889. The preliminary programme contains a list of thirty-five papers by eminent physicians from the North and South.

DR. SAMUEL WOLFE, of Skippack, Pa., will fill the Chair of Physiology at the Medico-Chirurgical College of Philadelphia during the coming year.

APPOINTED PROFESSOR OF PATHOLOGY.—At the last meeting of the Faculty of the Medico-Chirurgical College, Philadelphia, Dr. Ernest Laplace was appointed Professor of Pathology. Professor Laplace is a native of New Orleans and a graduate of the Literary Department of the Georgetown University, D. C. After several years' study in Tulane University and the Charity Hospital he went abroad and graduated in the Faculté de Médecine de Paris, where he studied under Pasteur and Cornil. He afterward spent several months in Vienna under Billroth and Stricker, and a year in Berlin with Koch and von Bergmann. While with Koch he discovered the superior efficiency as a germicide of acid sublimate of mercury and the sulpho-carbolic acid as a disinfectant. After his return to New Orleans

he instituted a Pasteur laboratory for the treatment of hydrophobia, and was elected visiting surgeon to the Charity Hospital. At the time of his call to Philadelphia he was Professor of Physiology and Hygiene in the High School Department of the Tulane University, and Demonstrator of Microscopical Anatomy and Bacteriology in the Medical Department of the same school.

HOSPITAL BEQUEST.—By reason of a bequest made by Mr. Wm. Thaw, one of the wealthy citizens of Pittsburg, the sum of one hundred thousand dollars is appropriated for the benefit of the hospitals of that city.

#### FOREIGN.

THE INTERNATIONAL CONGRESS of Hydrology and Climatology will open at Paris October 3, 1889. Numerous excursions to points of interest are among the features offered for this occasion.

A SCIENTIFIC MISSION.—Dr. Viault, Professor of the Medical Faculty of Bordeaux, has been charged with a mission to the high plateaus of Peru and Bolivia, where he is to continue the experiments of Paul Bert relative to rarefied air.—*Le Bulletin Médical*.

ANTISEPTIC PROPERTIES OF TOBACCO SMOKE.—Hajek, of Vienna, and Tassinari, of Pisa, have demonstrated by experiment that tobacco smoke destroys germs, and the former has found, by consulting statistics, that men who smoked were far less susceptible to infection than the remainder of the population during an epidemic of diphtheria. The *British Medical Journal* now endeavors to explain the latter fact, pointing out that the robust men who can tolerate large amounts of tobacco are the very ones who resist infection any way; it also advises non-smokers not to put their trust in the antiseptic pyridine of tobacco, and not to make themselves unwell during epidemics while attempting to habituate themselves to the use of the weed.

PHARMACY REGISTRATION IN FRANCE.—The Minister of Commerce has given notice that no pharmacist will be permitted to take his oath before reaching the age of 25 years, and in order to secure the rigid enforcement of this measure the university authorities have received orders to confer no diploma (without which young students are unable to establish themselves) until the proper age has been attained.—*Le Bulletin Médical*.

## TOPICS OF THE WEEK.

## THE INTERNATIONAL MEDICAL CONGRESS OF 1890.

As organizing committee of the International Medical Congress to be held in Berlin next year, Professors Virchow, von Bergmann and Waldeyer have issued the following resolutions: The Congress is to be opened on August 4 and closed on the 10th. It is to consist of diplomated physicians and surgeons who have registered themselves as members and have taken tickets of membership. The registration fee is twenty marks, and each member will receive a copy of the Transactions. The purpose of the Congress is purely scientific, and its business will be transacted in Sections. The Committee of Organization will cause the definitive officials to be elected in the first sitting of the Congress—namely: a President, three Vice-Presidents, and an indefinite number of honorary Presidents and of Secretaries. In the first sittings of the various Sections a President and a sufficient number of honorary Presidents will be elected, the latter to preside alternately with the former. Owing to the difference of language, a sufficient number of Secretaries will be appointed from among the foreign members. After the Congress the Transactions will be edited and published by an Editing Committee appointed by the presiding officials. The general sittings are intended for debates regarding the work and general relations of the Congress, and for addresses and communications of general interest. Such addresses are to be delivered only by members requested to do so by the Committee of Organization. Proposals relating to the work of the Congress must be made to the said Committee before July 1, 1890. The Committee will decide whether they shall be adopted or not. All discourses and communications in the general and in the Sectional meetings must be delivered to the Secretaries in writing before the close of the sitting. The Editing Committee will decide whether and in what compass these writings are to be printed in the Transactions. The official languages used at all meetings will be German, English and French. The by-laws and programmes will be printed in all three languages. It is permitted, however, to use another language at the meetings for brief remarks, provided that one of the members present undertakes to communicate the meaning of such remarks in one of the official languages. Introductory discourses in the Sections are to be limited, as a rule, to twenty minutes; in discussion only ten minutes are allowed to each speaker. Students of medicine and other persons of both sexes who are not physicians, but feel interested in the debates, may be invited by the President, or may receive permission to attend the sittings.

## THE FOURTH INTERNATIONAL PRISON CONGRESS.

Over and above its great interest to the student of State Medicine, this Congress, which is next year to meet at St. Petersburg, will have special attractions for the Englishman. Coinciding as it does with the centenary of John Howard's death, it will be utilized for the bestowal of international honors on that noble philanthropist.

The Government of the Czar, bearing in mind the fact that it was on Russian soil—at Kherson in fact—that Howard met his death in 1790, desires to show its appreciation of his philanthropic work by offering a prize for the best monograph on "The part filled by John Howard in the History of Penitentiary Reform." Competitors must write in the Russian or French language, and their work must include a biography of John Howard and a review of his publications; a characterization of penitentiaries at Howard's time, and a full list of all the innovations completed or proposed by him in these institutions; an estimate of Howard's influence on the subsequent course of penitentiary reform; and a bibliography of all his writings. Competing monographs must by May 1st (*i. e.*, according to the Russian almanac, the 15th), 1890, at latest, be in the hands of "The President of the Organizing Committee of the Fourth International Prison Congress at St. Petersburg." They must be furnished with a motto, and accompanied with a sealed letter containing the writer's name and address. The jury which will examine the monographs will be selected by the Congress itself, and it will award two medals of gold, a larger and a smaller, as well as silver medals and certificates of honorable mention. The competitor to whom shall be adjudged the larger gold medal will also receive 2000 fr. (£80), and his monograph will be inserted in the Proceedings of the Fourth Congress, while he will also have the right of reprinting it. All competing monographs, whether printed or in writing, which have not been withdrawn within two years by their authors are to be destroyed; and, lastly, the result of the Competition will be published in the Bulletin of the International Penitentiary Committee, and also in the Proceedings of the Fourth Congress. Besides the above-mentioned competition, there will be another at the instance of the conductors of the *Prison Discipline Review*. Its subject is the following: "What in the most civilized nations has been the historical development of the institutions relating to the correctional education of minors who have been convicted of crimes at common law, or who have been put in custody for idleness and vagabondage, or with a view to paternal discipline?" The conditions of the competition are identical with those of the preceding, except the following modifications. The competing monographs, in writing or in print, may be written in any language, but there must be a French translation of the same appended. The successful competitor will receive as prize the sum of 2000 francs (£80) from the conductors of the *Prison Discipline Review*. The Organizing Committee of the St. Petersburg Congress will be entitled to publish the successful monograph in the Proceedings of the Fourth Congress, while the author, will, at the same time have the right of reprinting it.—*The Lancet*.

## THE INHALATION OF DUST.

DR. KUNZE, in his inaugural thesis for the M.D. degree in the University of Kiel, publishes as a contribution to the diseases caused by the inhalation of dust a series of examinations of lungs so affected. In all these dust was

found microscopically, and after chemical tests in the various anatomical and histological parts of the lungs and in the interior of the lymphatic vessels numerous leucocytes were found covered with the dust. Being arrested in its progress, it causes inflammation producing hyperplasia of connective tissue, especially where a dense network of lymphatic vessels exists. Dr. Kunze also proved that the degree of alteration in so-called "dust lungs" depends not merely on the quantity of the dust inhaled, but also on its greater or less morphological power of injuring the tissue. He concludes from his experiments that even the greatest alterations in these lungs—such as nodes, indurations, and vomicae—are mainly produced by the inhaled dust, and that tuberculosis is only an occasional coincidence. The least serious alterations in the lungs resulted from the inhalation of lamp-black, the particles of which are very fine and little injurious; the most serious, from dust inhaled by earthenware manufacturers and stonemasons. The lungs of a locksmith showed only a moderate hyperplasia of connective tissue, the dust consisting partly of the finest particles of iron. In a worker in oxides of iron the lungs were found full of small granules, and the morbid changes in the tissues were very considerable. The lungs of gold miners were generally indurated and atrophied; the dust in these cases is exceedingly fine. Sand produced numerous circumscribed hard nodules and thick indurations. In cloth manufacturers, the lungs, in spite of their contact with an enormous quantity of organic dust, presented but few indurations. In the lungs of two stonemasons induration and tuberculous disintegration were observed; all the other lungs were entirely free from tuberculosis of any kind, an observation which was verified by the absence of tubercle bacilli in the muco-pus in the vomicae. —*Lancet*.

#### DISINFECTION.

The following practical remarks upon the important subject of disinfection are abstracted from an address delivered by FRANKLIN PARSONS, M.D., at the annual meeting of the British Medical Association at Leeds, in August, 1889:

For the disinfection of the discharges of the sick chemical agents must, as a rule, be used, though the discharges from the throat and nostrils in diphtheria and scarlatina are best received upon pieces of rag and burnt. It is of prime importance that infectious discharges should be disinfected immediately on being passed from the body, both because delay will give them more opportunity of causing mischief, and also because if the infected matter be mixed with a large quantity of other organic matters, as in a drain or privy, before the disinfectant is applied, the action of the latter will have to be exerted on a greater mass of material, and its effect will be *pro tanto* weakened; and the chances will also be great that portions of the infected material will escape its action. It is thought by some that germs of enteric fever, for instance, may long lurk unsuspected in defective drains and privies until some accidental circumstance, such as disturbance of the contents, brings them

into activity, and that many of the "sporadic" cases of this disease thus arise.

Of chemical disinfectants for the disinfection of excreta, corrosive sublimate is probably the most trustworthy and suitable for ordinary use. In its use, however, three precautions have to be borne in mind: 1. It is very poisonous, and hence, in order to avoid accidents (such as frequently occur with carbolic acid), the solution should be colored, as with permanganate of potash, sulphate of copper, or aniline blue. 2. It corrodes iron and other common metals, and is instantly decomposed by contact with them; hence it must be used in non-metallic vessels. 3. It forms with albumen an inert insoluble compound, but this may be prevented by acidulating the solution. A solution suitable for disinfection of excreta, clothing, etc., is made by dissolving half an ounce of corrosive sublimate with one ounce of hydrochloric acid and five grains of aniline blue in three gallons of water.

Chloride of lime is a useful disinfectant for excreta, but too strong a solution injures clothing. Carbolic acid is especially an antiseptic, retarding putrefaction, for example, in sewage, but a 5 per cent. solution is recommended by Koch by preference for disinfecting excreta and soiled linen of cholera patients. Creolin, a substance allied to carbolic acid, is said by recent experimenters to exceed it in destructive action upon spores of bacilli, at the same time that it is not poisonous to human beings. Permanganate of potash is an excellent deodorant, and has the advantage of not being poisonous. It is also, to some extent, a true disinfectant, but its action upon infective matter is much weakened when this is mixed with a quantity of other organic matter. Green copperas (ferrous sulphate) is a cheap deodorant, but, according to Koch, is not a disinfectant proper. Its habitual use for flushing sewers in time of cholera was strongly recommended by Dr. Budd, and was said at Bristol to have produced excellent results.

With regard to the disinfection of clothing, bedding, etc., used by the sick, it may in the first place be pointed out that for such articles as will stand it, boiling in water for say five minutes is an effectual means of disinfection. And since the infectious matters are not actually incorporated with the fibres of the fabric, but merely attached as dirt to their outside, there is reason to think that even a thorough ordinary washing will be a sufficient disinfection, so far as the articles themselves are concerned; but the infectious properties are transferred to the water in which they have been washed. The dangerous properties of such water are shown by the frequency with which cholera is contracted by those who wash the linen of cholera patients, and by cases like that at Moseley, recorded by Dr. Ballard, where an outbreak of enteric fever occurred among the persons drinking the water of a well into which had percolated the soapsuds in which the soiled linen of an enteric fever patient had been washed. To avoid such risks it is necessary that infected articles which are washable should be disinfected before being washed; this should, for obvious reasons, be done immediately on their being left off. Boiling might be used for this purpose, but boiling water in sufficient

quantity is not always at hand; and again, if soiled clothes are boiled, the coagulation of albuminous matters fixes stains in them and spoils their color. Hence it is more convenient to put the clothes to steep in some chemical disinfecting solution, of which a painful should be kept in readiness. A solution of corrosive sublimate is the best for this purpose, as, besides being the most effective, it has the advantage that it does not stain or rot the linen. When the grosser dirt has been removed by rinsing in water, the articles may be boiled.

Articles which cannot be boiled in water without injury, such as cloth clothes, blankets, and beds, are best disinfected by exposure to heat, and the experiments which I have quoted show that for this purpose a steam heat is preferable to a dry heat for several reasons, especially because a lower temperature and a shorter exposure suffice to kill infective organisms, and because a steam heat penetrates much more rapidly than a dry heat into bulky and badly conducting articles. Further advantages are that in a steam apparatus the temperature is approximately equal in all parts, that it can be accurately ascertained and kept constant at any required degree for any length of time—conditions which are essential to a good apparatus, but which are very difficult to obtain where dry heat is employed. . . .

As regards disinfection of food, no one would, I presume, willingly eat or drink articles that he knew to be infected. As, however, one cannot always guarantee the absence of infection in the viands we eat or the water or milk that we drink, it is satisfactory to know that boiling or thorough cooking may be trusted to secure complete disinfection. In the experiments I have quoted it was found that even the very refractory spore-bearing bacilli of anthrax were destroyed by one minute's boiling in water at 212° F., though certain non-pathogenic bacilli found in vegetables and milk require for sterilization a higher temperature or more prolonged boiling, a fact familiar to the housekeeper who makes jam. It is, doubtless, owing to the efficiency of cooking as a disinfectant that sanitarians in France and Germany, where milk is, I believe, always boiled before use, are sceptical as to the possibility of the propagation of infectious disease by that medium; whereas with us in England, where milk is drunk raw, epidemics of milk origin are a matter of almost everyday experience. On the other hand, trichinosis, so common among the Germans, who eat their ham raw, that it has to be guarded against by an elaborate system of microscopic examination of all slaughtered swine, is practically unknown as a human disease in England and France, where meat is always cooked. . . .

For house disinfection, fumigation with sulphurous acid or chlorine gas, the latter preferred, followed by thorough cleansing and scrubbing, removal of wall-paper and lime-washing, are to be recommended; but these processes, to be effectual, need to be carried out with more thoroughness than is frequently done. A difficulty often met with is to know where the inmates are to go while the house is being disinfected; and it would be useful for this and other purposes if sanitary authorities had power to provide refuges for people whom, although not themselves sick, it might be desirable to remove from their homes.—*British Medical Journal*.

## SOCIETY PROCEEDINGS.

### Mississippi Valley Medical Association.

*Fifteenth Annual Meeting, held at Evansville, Indiana, September 10, 11 and 12, 1889.*

#### FIRST DAY—MORNING SESSION.

THE PRESIDENT, DR. GEO. J. COOK, of Indianapolis, Ind., in the chair.

After the usual address of welcome the President made a few remarks, saying that on account of the large number of papers on the programme he would not present the usual Presidential Address.

The first paper presented was by DR. G. V. WOOLEN, of Indianapolis, on

#### NASAL DIFFERENTIATION.

The author arrived at the following conclusions:

1. The nares should not be regarded as a whole in relation to etiological factors.
  2. Their correct interpretation must be with regard to their anatomical and pathological characters.
  3. The regions of the inferior turbinates are the seats of hypertrophies which are the essential pathological factors of hay fever.
  4. The posterior tips of the inferior, and frequently middle turbinate are likewise the seat of hypertrophies which are the essential pathological factors of asthma and its congener.
  5. That this is true primarily because the sensory apparatus of these parts is essentially distinct.
  6. These products do not become factors in hay fever and asthma except there be a special dyscrasia.
  7. Other reputed causes of asthma are associated products of hypertrophic disease of the nares and may have led to confusion as to cause, and may possibly have been reported prematurely, if hypertrophy were not removed.
  8. The anterior tips of the middle turbinate are the seat of hypertrophic disease which produces much nerve disturbance which is attributed to various other causes.
  9. By pressure of these hypertrophies on the nasal nerves we get the chief results in neuralgias in the region of distribution of the first division of the fifth pair of cranial nerves, and by obstruction of the orifices of ducts of anterior ethmoidal cells and frontal sinuses this is greatly intensified.
  10. Thorough removal of these hypertrophic products is the only radical cure for these various affections.
- In the discussion that followed DR. WM. PORTER thought that clinically there were exceptions to the conclusions arrived at in the paper.
- DR. DUDLEY S. REYNOLDS said that many persons had hypertrophy of the turbinated bones

without asthma, and in many cases of asthma the excision of the hypertrophied tissue did not relieve the asthma. To say that any case of asthma or hay fever is caused by hypertrophy of the turbinated bones he considered an error.

DR. WOOLEN in closing the discussion said that in every case his theory had been found correct. It is not the *magnitude* of the hypertrophy but the fact that hypertrophy exists, that causes the disorders, and the thorough removal of every portion of the hypertrophic tissue was in every instance followed by complete recovery.

DR. J. M. MATHEWS, of Louisville, read a paper on

#### A SIMPLER METHOD OF TREATING FISTULA IN ANO,

and showed a fistulotome, a new instrument of his own invention, for use in certain cases where patients would not submit to operation by the knife. The instrument is used to dilate and straighten fistulous tracts, and carries a concealed knife which can be used if necessary.

DR. MURDOCK thought that but for a small and very select class of cases the instrument and method of treatment would be of little avail. The fact that the sphincter could not be put to rest was the chief objection to all non-cutting methods. If the sphincter can be divided and thorough drainage secured fistulous tracts heal as readily as any other.

DR. GRANT, of Louisville, thought that the use of ligatures was to be condemned, and in but few cases would the method of treatment of Dr. Mathews be of practical benefit on account of the lack of perfect drainage.

DR. WATHEN, of Louisville, differed in opinion as to the cause of non-union of fistulous tracts, viz.: the contraction of the sphincters. This is probably the cause of irritation, but certainly does not prevent union. The important point of securing primary union can almost always be secured by using the deep buried animal sutures, the same as the deep perineal suture. If the sphincter is thoroughly divulsed no division of the sphincter will be necessary in many cases. The pyogenic membrane must be dissected out and the parts thoroughly brought together, and primary union will occur.

DR. ARCH. DIXON, of Henderson, Ky., believed that the method of Dr. Mathews could not be compared with the advantages to be gained by the thorough use of the knife. The knife is the only radical cure.

DR. J. M. MATHEWS in closing the discussion agreed with the expressed opinion that the use of the knife constituted the best method of treatment, but there are many cases where the patient will not submit to the knife, and for those cases the method of dilatation and drainage had proved beneficial in many cases.

On motion the Society adjourned to 2 P.M.

#### AFTERNOON SESSION.

DR. A. S. BARNES, of St. Louis, read a paper on  
THE ACCOUCHEUR AND HIS FORCEPS.

The author advocated the more frequent use of the forceps in difficult or delayed labor, believing that by their use the comfort of the mother and safety of the child are promoted. He never uses ergot after delivery and disapproved of the use of anæsthetics in labor.

In the discussion DR. W. H. WATHEN, of Louisville, asked as to the percentage of stillborn children in forceps cases. He had tried in vain to secure statistics on the subject. He believed that the statistics of Cæsarean section (93 per cent. of living children) were as good as those of forceps delivery.

DR. BELL said that there were two indications for interference with forceps, the danger to the mother and the danger to the child. The danger to the child can always be determined by the location of the fetal heart sounds. Real danger to the child should be the rule in every case for the use of forceps.

DR. MURDOCK, of Pittsburg, Pa., believed that forceps had contributed very much to the lessening of the pains of labor. Every physician should use them more frequently; even for his own comfort their use was justifiable.

DR. DIXON, of Henderson, Ky., thought that the number of cases reported, 128 per year for thirty-five years, was remarkable, and that the conclusions should be of value as to the statistics of stillborn children.

DR. BARNES in closing the discussion said that the use of chloroform complicated labor, that both the long and short forceps should be a part of the obstetrical armamentarium of every obstetrician, as by the use of the short forceps in many cases the woman could be delivered without change of position.

DR. B. MERRILL RICKETTS, of Cincinnati, read a paper on

PLASTO-COSMETICS IN SURGERY OF THE FACE, in which he made three classifications: 1. Removal of malignant growths. 2. Correction of deformity due to the loss of parts from either congenital or traumatic causes, or from previous operations, or diseases of any kind, including pug nose and ptosis. 3. The removal of nævi, warts, moles, hairs, pigmentary deposits, cicatrices, alveola fistulae, enlarged glands, or anything abnormal, other than malignant growths, that may appear on the face or neck. He spoke of the different operations now resorted to to correct the various kinds of deformity such as are indicated in this classification, such as thick lips, ears, lids, and alæ, the grafting of cartilage, skin and bone, electrolysis, the natural chlorides, and the substitution of various kinds of tissue.

The paper was discussed by Drs. I. N. Bloom, of Louisville, Ky., and G. H. Rohé, of Baltimore.

DR. S. E. MUMFORD, of Princeton, Ind., read a paper on

PERINEORRHAPHY—ITS IMMEDIATE OPERATION, in which the advantages of the early operation, not later than twenty-four to thirty-six hours after delivery, were clearly set forth.

DR. L. WORSHAM, of Evansville, believed that the immediate operation was of decided advantage in the majority of cases.

DR. JOSEPH EASTMAN, of Indianapolis, said there were at times conditions present which are impossible to operate immediately with success.

DR. BELL thought that in conditions of uræmia, œdema and the like, immediate operation for restoration of the perineum was not advisable. In his opinion the most frequent cause of laceration of the perineum was not the head, but the shoulder.

DR. W. H. WATHEN, of Louisville, believed that it was impossible for anyone to do a large obstetric practice without occasional ruptures of the perineum. He believed that the efforts to prevent rupture had been the cause of more ruptures than it had prevented. He advised in cases of complete rupture the use of the kangaroo tendon sutures.

DR. I. N. LOVE, of St. Louis, read a paper on

#### ANTIPYRETICS, ANALGESICS, AND SEDATIVES,

referring especially to antipyrin, antifebrin, and exalgin, as the most recent additions to the list. He prefers acetanilid (antifebrin) to antipyrin, and had most happy results from the use of exalgin.

DR. MUMFORD warned physicians against the use of antipyrin in the continued fevers, believing that its continuous administration was detrimental.

DR. SMYTHE, of Greencastle, Ind., insisted on the necessity of the high temperature being controlled by antipyrin, or some similar agent, to prevent fatty and parenchymatous degeneration taking place as a result of high temperature. He believed that the continued use of acetanilid and similar agents in continued fevers was detrimental to the patient.

DR. E. LINTHICUM, of Evansville, had had an unfavorable experience with exalgin, believing it inferior to the other agents of its class.

DR. J. H. HOLLISTER, of Chicago, had had occasion to regret the use of antipyrin in decided pyrexia. He had used acetanilid and quinine with decided benefit.

DR. J. L. GRAV, of Chicago, had used acetanilid in epilepsy with decided benefit, and believes it superior to the bromides in the majority of cases.

DR. DUDLEY REYNOLDS, of Louisville, believed that the use of agents which merely reduce temperature was not a scientific treatment of disease,

and their influence on mortality was not marked.

On motion, the Association adjourned to 9 A.M. Wednesday.

#### SECOND DAY—MORNING SESSION.

The first paper was by DR. W. C. CHAPMAN, of Toledo, Ohio, on *Prognosis in Pulmonary Diseases*; DR. C. F. MCGAHAN, of Chattanooga, Tenn., followed with a paper on *Treatment of Pulmonary Phthisis*; DR. F. C. WILSON, of Louisville, read a paper on *Differential Respiration*, exhibiting a new apparatus for systematic lung exercise; DR. EDWIN RICKETTS, of Cincinnati, reported a case of *Tubercular Peritonitis with Tubercular Fallopian Tubes*; and DR. WM. PORTER, of St. Louis, read a paper on *Contagiousness of Tuberculosis*.

The first paper, that of Dr. Chapman, was a plea for more energetic treatment of the disease as a local disease, believing that thereby a more favorable prognosis was possible. Dr. McGahan believes that the climatic treatment of phthisis offers the best results, that every case of phthisis should, upon the discovery of the disease be removed from the locality in which it developed. The climate of South Carolina is best adapted to such cases. Dr. Porter believes that the latest opinions uphold the theory of the contagiousness of tuberculosis.

Dr. Ricketts cited 100 cases of tubercular peritonitis that had been treated by abdominal incision where 25 cures, from nine months to twenty-five years, had taken place, claiming that enough operative evidence has been given to positively assert that lives have been prolonged, and suffering greatly relieved, and that bolder and prompter surgical measures are justifiable. The Doctor's case presented for consideration: 1. Failure to diagnose the trouble previous to abdominal incision. 2. The lowering of pulse and temperature as a result of the operation. 3. The non-recurrence of dropsical fluid. 4. Fragile condition of tubal tissue and proneness to bleeding upon the slightest abrasion. 5. Good results obtained (hæmostatic) in the application of perchloride of iron.

Discussion was had upon all the papers bearing on the subject.

DR. THEODORE POTTER, of Indianapolis, said that the disease is not commonly hereditary; it is a local disease and only accidentally becomes a general disease. He believed that a child never emerged from its mother's womb with tuberculosis. Statistics are very unreliable as to heredity and are easily misinterpreted.

DR. WOOLEN, of Indianapolis, said that until the question of heredity was settled no conclusion could be arrived at. Can disease be hereditary? Most emphatically, no. But there is a type of constitution which may be transmitted. This

vulnerability of constitution may be hereditary, but to presuppose that a germ of disease can be transmitted through the spermatozoa or ovum through foetal life is entirely unreasonable.

DR. DUDLEY REYNOLDS, of Louisville, believes that the choicest food for the development of the bacillus is the lymph corpuscle. The inhalation of the bacillus through the imperfect air passages carries the disease to the lungs.

DR. JOSEPH EASTMAN, of Indianapolis, thinks the most important treatment is the improvement of the vital forces. Latent syphilis is the cause of many cases of tubercular peritonitis.

DR. J. A. LARRABEE, of Louisville, said that the predisposing and the exciting cause must be present in every case. As to the theory of micro-organisms, they are present everywhere. They are not essentially the disease. He does not believe it is a case of tuberculosis unless the bacilli are present. The matter of lung exercise is of the greatest importance, giving, as it does, apex expansion.

DR. CHAPMAN said that the question of heredity was not one of transmission of disease, but of constitution. This is proved by the fact that the disorder skips one generation frequently.

DR. MCGAHAN said that he did not believe in heredity in consumption.

DR. PORTER said that he did not believe that the direct inheritance of tuberculosis was proven. Chest exercise is of the greatest importance. Good tissue is the best antidote to the bacillus.

DR. L. BAUER, of St. Louis, read a paper on *Recto-Vesical Lithotomy*, after which the Association adjourned to 2 P.M.

#### AFTERNOON SESSION.

DR. A. B. SHAW, of St. Louis, read a paper on

#### SUSPENSION IN AFFECTIONS OF THE SPINAL CORD,

and exhibited a Suspension Apparatus which he has devised. The apparatus is a modification of the Sayre and Varity apparatus.

DR. LEWIS, of Kansas City, had seen many suspensions at Hot Springs, Ark., and had himself undergone the treatment with beneficial results.

DR. RYAN, of Cincinnati, did not believe that any stretching of the cord took place.

DR. VANCE, of Louisville, thought that any stretching which might occur would be ligamentous, that the cord could hardly be affected.

DR. SHAW, in closing the discussion, said that in cases of locomotor ataxia, certain cases of cerebro-spinal sclerosis, and old cases of myelitis were benefited by the treatment. Paralysis agitans was not benefited.

DR. H. C. DALTON, of St. Louis, read a paper on the subject

#### IS SENN'S HYDROGEN GAS TEST INFALLIBLE?

He reported several cases in which the gas test failed, and one in particular, of a Chinaman with bullet wounds of the stomach, in which the stomach was partially filled with rice and the inflation by gas simply plugged the bullet holes in the stomach and prevented the effectiveness of the test.

DR. EASTMAN said that he had used the sulphuretted hydrogen gas in preference to the ordinary hydrogen, as its odor was more persistent and seemed to better answer the demands. He had had a number of failures of the gas to ignite.

DR. H. O. PANTZER, of Indianapolis, read a paper on

#### RUPTURE OF OVARIAN CYST,

with report of a case in which death occurred before operative interference was had. A pedicle was found, post-mortem, which was twisted to the left. A diagnosis of twisted pedicle was made ante-mortem.

DR. A. M. CARTLEGE, of Louisville, presented a paper on *A Case of Ovarian Tumor*.

In the discussion that followed the two papers DR. EASTMAN said that he had seen the twisted pedicle case before death, in consultation, and considered the diagnosis one of extreme difficulty.

DR. RICKETTS said that the matter of twisted pedicle was to be explained by the fact that before the tumor became adherent there was pressure upon the colon, and in the passage of feces the tumor was gradually turned to the left, and thus the pedicle became adherent. This can occur only where the pedicle is long. Senn's test he found faulty frequently. Then the distension of the intestines by the gas and their replacement was a matter of great difficulty.

DR. VANCE, of Louisville, endorsed the views of Dr. Dalton as to the unreliability of the gas test.

DR. STEELE said that he had a case in which the gas test was applied. It would not ignite. The patient asked to have laparotomy performed. It was done, and eleven holes were found in the small intestines.

DR. BRANSFORD LEWIS, of St. Louis, read a paper on the *Rational Treatment of Gonorrhoea*, which was followed by a paper on *Excision of the Knee for Convenience*, by DR. AP. MORGAN VANCE, of Louisville. DR. G. W. RYAN, of Cincinnati, presented a paper on *Orthopaedics in Infantile Paralysis*, after which the Association adjourned to 9 A.M. Thursday.

#### THIRD DAY.

The Committee on Nominations reported the following officers for the ensuing year: President, Dr. J. M. Mathews, Louisville, Ky.; 1st Vice-President, Dr. C. R. Early, Ridgway, Penna.; 2nd Vice-President, Dr. T. B. Harvey, Indianapolis.

Ind.; Secretary, Dr. E. S. McKee, Cincinnati, O.; Treasurer, Dr. F. McGahan, Chattanooga, Tenn.

The next meeting will be held in Louisville, Ky., the second Tuesday in September, 1890.

Papers were read by DR. A. J. THOMAS, of Indianapolis, on *The Insane of Indiana—their Care and Treatment*; by DR. D. A. THOMPSON, of Indianapolis, Ind., on *Some Forms of Eye Trouble*; by DR. S. S. BISHOP, of Chicago, on *The Abortive Treatment of Acute Naso-Pharyngeal Catarrh*; by DR. O. EVERTS, of Cincinnati, on *The Treatment of the Insane as Related to Other Conditions of Society*; by DR. G. F. LYSTON, of Chicago, on *Apparent Concretions, Transformations of Syphiloma of the Tongue*.

## FOREIGN CORRESPONDENCE.

### LETTER FROM PARIS.

(FROM OUR REGULAR CORRESPONDENT.)

*Professor Peter on the Necessity of Antiphlogistic Treatment at the Onset of Acute Pneumonia and Acute Pleurisy—Professor Lépine reports a Curious Case of Cerebral Accidents determined by a Hæmatoma and Cured by Trephining—Dr. Constantin Paul's Researches on the Action of Saccharin—Dr. Maurice Perrin.*

Professor Peter lately delivered a very interesting clinical lecture at the Necker Hospital, on the necessity of the antiphlogistic treatment at the onset of acute pneumonia and acute pleurisy. The lecturer said that he was induced to take up this subject owing to the neglect, now-a-days, of this precious measure in properly selected cases. If, he said, our predecessors bled to much, we have gone to the opposite extreme, much to the prejudice of the patients. He based his present lecture on a case in his ward in which the patient was affected with pleurisy accompanied with effusion, for which he was, for the fourth time, being tapped. This might have been obviated if the antiphlogistic treatment had been adopted at the commencement. Professor Peter is one of the few physicians of the Paris Faculty who employ the antiphlogistic treatment in these and other cases in which it was formerly adopted, but it is owing to the divers theories where bacteriology plays a preponderating rôle, it has been wrongfully abandoned. By antiphlogistic medication the lecturer not only referred to drugs, but included bleeding, cupping after scarifications, leeches and blisters, the latter being applied in a later stage of the acute inflammatory affections. He cited the teachings and practice of such men as Andral, Bouillaud and Grisolle in support of his own practice, although he must admit that Bouillaud, by his exaggeration of this treatment, did much harm both to the cause that he advocated and to the patients, a reaction in the pro-

fession was produced, and the antiphlogistic method fell into disuse. The introduction of bacteriology has struck the last blow to this mode of treatment. At the present moment, pneumonia is considered a microbial malady. The consequence is, one sees only this microbe, which it is necessary to kill, whence the idea of practicing injections into the lungs; but it was scarcely possible, in all the cases, to reach in this way the microbes. It is sufficient, in leaving only a few, for a rapid multiplying of the microbes to take place. This system was soon abandoned; but the misfortune is that these theories do not lead to any useful medication. Professor Peter concluded his lecture by repeating his injunction of slight depletion in all cases of acute pleurisy. If phlebotomy is objected to, scarifications followed by cupping glasses may be employed, or a few leeches to the number of from six to ten may be applied, and thus prevent effusions, or the malady becoming chronic. In the same way, he finds that when pneumonia is treated in a proper manner, cures rapidly. He believes that cases of chronic pneumonia have become more frequent since the abandonment of the antiphlogistic method.

Professor Lépine, of Lyons, lately reported to the Academy of Medicine a curious case of cerebral accidents determined by a hæmatoma and cured by trephining. The patient was a man of 29 years of age, alcoholic, and for five years he was subject to epileptiform fits which were attributed to a fall. He soon got into a comatose state which was followed by complete aphasia and slight hemiplegia of the right side. Trephining was decided upon, as the state of the patient was not improving. The operation was performed ten days after the accident, about the level of the ridge of Rolando. At the moment when the dura mater was incised, about 25 grams of liquid of a chocolate color spouted out with some force. On the next day, the patient was able to write his name, and in a few days later the aphasia and the hemiplegia disappeared. But notwithstanding the success of the operation in this case, Dr. Lépine is of opinion that it should be practiced with great prudence and reserve.

Dr. Constantin Paul has lately made some new researches on the action of saccharin. It results from his new experiments that the antiseptic power of saccharin diminishes by the addition of alkalis. The maximum antiseptic effects are obtained when the saccharin is directly incorporated in a state of powder in the nutritive medium, the latter being in general sufficiently alkaline to dissolve the saccharin. The therapeutic consequences of these facts are as follows: When it is wished to employ saccharin as a sweetening substance, an equal proportion of the bicarbonate of soda should be added to it, and then there would be no fear of the gastric troubles sometimes com-

plained of by certain diabetic subjects. The saccharinate of soda may be administered to the extent of 5 grams. Should, on the contrary, a strong antiseptic action be required, pure saccharin in powder should be employed. If, however, it is intended for the microbe of putrefaction or of suppuration, the proportion of 2 parts of the bicarbonate of soda with 3 of saccharin, renders the saccharin very soluble and permits it to arrest the development not only of these two microbes, but of all the numerous microbes which live in the mouth and possess the property of fluidifying gelatin. Saccharin rendered soluble in these proportions constitutes a valuable mouth-wash.

Military Surgery has just sustained a great loss in the person of one of its most illustrious representatives, Dr. Maurice Perrin, who died at Vezelise, his native town, on the 31st of August, last, after a very short illness. He was Inspector-General of Military Hospitals, President of the Academy of Medicine, and Commander of the Legion of Honor. Born on the 13th of April, 1826, after having prosecuted his studies at Nancy, he came to Paris in 1851, and took his degree of Doctor of Medicine. In 1858 he was appointed, after competition, Agrégé of Val-de-Grâce; and ten years after he was elected Professor of Operative Surgery. His most remarkable works consist in his studies of the psycho-chemical action of anæsthetic substances, on the rôle of alcohol and of anæsthetics in the organism, *Treatise of Surgical Anæsthesia*, *Treatise of Ophthalmoscopy and Optometry*. He was elected Member of the Academy of Medicine in 1875, and raised to the Presidency in 1889.

A. B.

## DOMESTIC CORRESPONDENCE.

### A Tribute to Dr. Samuel Jackson.

*To the Editor:*—The writer, who in the winter of 1862-3 attended the last course of lectures that Dr. Samuel Jackson delivered at the medical department of the University of Pennsylvania, remembers that distinguished lecturer well, and recalls with what feeling he delivered his farewell address to the medical students of the class in the spring of 1863, when he forever bade farewell as a lecturer and retired from the chair of physiology. The tears ran down over his cheeks while he was speaking, and there were few dry eyes in the building. The decrepitude of age had crept upon him in the many years he had lectured in the university. He had lost the use of his lower extremities, so that he had to be carried to and from the chair from which he lectured. His hair was gray and his face wrinkled, but he was still lucid and fluent in his delivery. He had been Henry Clay's physician, and in his

discourse upon death, in the the lecture-room, told the story of how timid that great man expressed himself as being as to the pains of physical death. Dr. Jackson endeavored to soothe the mind of the great orator by saying that death takes place by such easy and gradual processes that it was entirely void of pain. He compared death with the going out of the flame of a candle that was burning in the room at the time, and which was flickering out for want of combustible material. He said: "Mr. Clay, you see how easily and slowly that flame is being extinguished; so it will be with you when dying—easy, gradual, painless."

In a visit I made to Dr. Jackson in the summer of 1865 he said to me: "I have always, during life, been a hard student, and one of the problems I have been unable to solve yet is how much inflammable matter in a given time the sun used in warming that space included in the solar system." But he stated further that, if unable to solve the problem in this life, in the next life, to which he was fast hastening, he hoped to be enabled to solve the problem, then and there.

At a speech that Dr. Samuel Jackson delivered at a reception given to Edwin Forrest at Philadelphia, Pa., in 1838, one who was present and heard the great speeches of the evening said: "The speech of Dr. Samuel Jackson was by all odds the gem of the evening. His diction was of the best, and a constant stream of eloquence bubbled from his lips. He appeared to be of imagination all compact, and his fancy seemed to be as free and boundless as the chainless wind. Striking figures and beautiful metaphors came at his call as readily as though he wielded the wand of the magician. His words, expressing the most beautiful thoughts, fell from his lips with the grace and readiness of water sparkling from a fountain. He spoke with great ease and rapidity, and to the then immature and inexperienced mind of the writer it was the most brilliant and eloquent speech. He has since heard the deathless three of America, Clay, Calhoun and Webster. He has listened with delight to George McDuffee, William C. Preston, John J. Crittendon, George Poindexter, Jefferson Davis and Edward Everett. He has hung enraptured many times over his utterances while that marvelous child of genius, Sergeant S. Prentiss, poured forth a stream of impassioned eloquence as resistless as the rush of the mighty river he loved so well, and on the margin of which he had his home. That imperial river, not inaptly termed "a great inland sea" by Mr. Calhoun, now flows by his grave; and its turbid billows, as they roll in solemn grandeur to the ocean, murmur an eternal requiem to the memory of the most eloquent orator of modern times, or, in my judgment, of any known period of the world's history. And yet,

having often listened to the great masters of eloquence whom I have named, the speech of Dr. Samuel Jackson, heard more than half a century since, still lingers in my memory, not only as a "thing of beauty," but "a joy forever."

JOHN M. BATTEN.

309 Fifth ave., Pittsburgh, Pa., August 9, 1889.

### Audi Alteram Partem.

To the Editor:—The making of punctures, exploratory and otherwise, through trephrated, instead of trephine openings, as described by Dr. Edmond Souchon, and referred to in your editorial of September 7th, is not new in any sense. It was carried out by me and its results described several years ago.<sup>1</sup> I have never claimed originality for it, as Gibier, if I remember rightly, employed trephration ten years ago, in the course of some inoculation experiments involving the brain. The apparatus used by me was an ordinary watchmaker's drill.

Respectfully yours,

E. C. SPITZKA, M.D.

712 Lexington Ave., New York, Sept. 7, 1889.

### BOOK REVIEWS.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR 1888. Vol. v. Edited for the Association by ALFRED LUDLOW CARROLL, M.D., of Richmond County. New York: J. H. Vail & Co., 1889. Pp. viii-610.

This is a volume of far more than ordinary interest, and we feel like congratulating the Association on the superior character of the work done and on the excellence with which the editor has performed his part. More than forty papers were presented at the meeting in question, and it is not too much to say that all are of a highly meritorious character. Of especial interest are the discussions of various important subjects in which the leading topics are considered *seriatim*, as for example the "Discussion on Puerperal Septicæmia." In this the "Introductory Remarks" were made by Dr. C. C. Frederick; then followed a series of six leading questions, some of them particularly comprehensive in character. Each of these questions formed the text of one or more short papers, in which the writers confined themselves closely to the immediate question under consideration; in this discussion the papers were read by Drs. H. M. Biggs, E. D. Ferguson, S. B. W. McLeod, A. L. Carroll, F. W. Ross, John Shradly, W. H. Robb, Frank Grauer, William T. Lusk and R. L. Banta.

The New York State Medical Association was founded in 1884, and has thus far been presided over by such distinguished men as Henry D. Dildama, John P. Gray, E. M. Moore, Isaac E. Taylor, John Cronyn and William T. Lusk. The membership has already reached the large figure of 681. It comprises five branch associations in the various sections of the State, between which the membership is pretty evenly divided.

### NECROLOGY.

Alexander T. Darrah, M.D.

DR. ALEXANDER T. DARRAH, of Bloomington, Ill., died at his home on September 4, 1889, after a short illness caused by congestion of the bowels. Dr. Darrah was born in Delaware, Ohio, in 1837, was graduated from Rush Medical College, Chicago and practiced medicine in Tolono, Ill., until 1883, when he removed to Bloomington. He enjoyed a deservedly high reputation as a physician and public spirited citizen. He was also very prominent in the Masonic fraternity, having been elected Grand Master of Illinois in 1886 and 1887. A wife and three children survive him.

### MISCELLANY.

EDISON'S IMPRESSIONS OF PARIS.—A correspondent of the *Scientific American* asked Edison: "How are you impressed with Paris?" "Oh, I am dazed. My head's all in a muddle, and I reckon it will take me at least a year to recover my senses. I wish now that I had come over in my laboratory blouse, and could have gone about unknown and have seen something. The exhibition is immense, larger than our Philadelphia exhibition. So far, however, I have seen but very little of it. This morning, however, I saw a tool which will save me \$6,000, clear, a year. It is a chisel worked by hydraulic pressure. I just saw it, passing by—just a glance. I shall order some, and send them out. They will enable us to reduce our labor by eighteen hands. What has struck me so far chiefly is the absolute laziness of everybody over here. When do these people work? What do they work at? I have not seen a cartload of goods since I came to Paris. People here seem to have established an elaborate system of loafing. Some of these engineers who come to see me, fashionably dressed, walking-stick in hand—when do they work? I don't understand it at all."

THE McLEAN COUNTY (ILL.) MEDICAL SOCIETY met at the office of Drs. Darrah & Corley on the 2d inst. There were present Drs. H. Parkhurst, F. J. Parkhurst, J. B. Taylor, F. W. Keyes, C. C. Sater, L. E. Spear, John Little, J. L. White, C. J. Corley, Rhoda Galloway, E. Mammen, S. T. Anderson, D. A. White, W. R. Shinn, N. F. Jordan, F. C. Vandervort. Drs. H. F. Ballard and W. L. Hallam were elected to membership. The application of Dr. C. E. Ballard, of Saybrook, for membership, was received and referred to the Board of Censors. Dr. E. Mammen exhibited with the microscope a piece of epithelioma; Dr. J. B. Taylor read a very able and interest-

<sup>1</sup> "On Some Points Regarding Therapeutical and Other Injuries of the Brain," Proceedings American Neurological Association, 1887. *Journal of Nervous and Mental Diseases*; also, *Journal of Comparative Medicine*, July, 1886.

ing essay on "The Faults of the Medical Profession." Dr. C. J. Corley's essay on "Urinalysis" was attentively listened to by all present. A vote of thanks was tendered by the Society to Drs. Taylor and Corley for the excellence of their papers. The President appointed Drs. D. A. White and F. J. Parkhurst as essayists for the October meeting, and Drs. W. R. Shinn and E. Mammen for the November meeting. The Society adjourned to meet on the first Monday in October.

THE PROFESSIONAL CANVASSER No. 3 is a thirty-two pages pamphlet combining a price list of the scientific medical periodicals of the United States and a concise consideration of the subject, "What can be done with old books?" Applicants for copies are solicited to remit six cents to cover costs of postage, etc. Address all communications to Fred. D. Van Horen, 23 Clinton Place, New York.

SENILE MICROBIO-MANIA.—The *Revue de Thérapeutique* says: A savant of Naples, Dr. Malinconico, has made a greater discovery than the famous elixir of youth of Brown-Séquard. The journals announce very seriously that Dr. Malinconico is about to discover the *microbe of old age*.

This microbe is transmitted, according to the Italian savant, by inheritance, invades with age the entire human organism, ravages and destroys it, producing old age, and finally death.

Dr. Malinconico hopes that he will be able to discover the means to combat, and finally to destroy, this terrible microbe, which will prevent men growing old. The savants are invaluable!—*Times and Register*.

PROGRESS OF SANITATION.—There are now thirty-nine crematories in various parts of the world. Italy leads easily with twenty-three, then comes America with ten, while England, Germany, France, Switzerland, Denmark and Sweden are satisfied so far with one apiece. In Italy there were two cremations in 1877; the number rose to fifteen in 1877, and in 1878 the number was 226. Since 1876, 1,177 cremations have taken place in Italy, whilst the combined numbers from other countries bring the total only to 1,269.

QUERIES WANTED.—At the San Francisco meeting of the American Pharmaceutical Association a resolution was passed requesting the members to propose such queries as they would like to see answered next year. Such queries should be forwarded at once to the chairman of the Section on scientific papers, H. M. Whelpley, St. Louis, Mo. Members who have decided to write papers should send the titles to the same address.

NEW YORK STATE MEDICAL ASSOCIATION.—The sixth annual meeting of this Association will be held at the Hotel Brunswick, New York, commencing next Wednesday and continuing three days. The programme contains a list of sixty-six papers, the writers of which are eminent and well-known members of the profession. The membership now numbers over 680 physicians and we have no doubt there will be a full attendance and a large accession of new members. Dr. J. G. Truax, 17 East 127th St., New York City, is the Secretary.

HEALTH IN MICHIGAN.—For the month of August, 1889, compared with the preceding month, the reports indicate that cholera morbus, dysentery, cholera infantum, diarrhoea, and typho malarial fever increased, and that rheumatism, neuralgia and inflammation of kidney decreased in prevalence.

Compared with the preceding month, the temperature in the month of August, 1889, was higher, the absolute and relative humidity were less, and the day and night ozone were more.

Compared with the average for the month of August in

the three years, 1886-88, bronchitis, cholera morbus and tonsillitis increased, and neuralgia and rheumatism were less prevalent in August, 1889.

For the month of August, 1889, compared with the average of corresponding months in the three years 1886-88, the temperature was slightly higher, the absolute and relative humidity were less, and the day and night ozone were more.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of August, 1889, at 21 places, scarlet fever at 18 places, typhoid fever at 40 places, and measles at 7 places.

Reports from all sources show diphtheria to have been reported in 5 places less, scarlet fever at 12 places less, typhoid fever at 22 places more, and measles at 6 places less than in the preceding month.

### LETTERS RECEIVED.

Dr. W. H. Atkinson, New York; Dr. W. K. Sutherland, Mansfield, Ia.; Prof. Schnitzler, Iosefstadt, Vienna, Austria; Dr. Thos. Eliot, Worth, Tex.; Dr. E. E. Montgomery, Philadelphia; Dr. C. H. Cook, Natick, Mass.; Dr. Frank H. Ingram, Chicago; Dr. Henry O. Marcy, Boston; Dr. John B. Hamilton, Washington; Dr. W. A. Scott, Swanton, O.; Dr. William H. Morrison, Philadelphia; Dr. H. Judd, Galesburg, Ill.; Dr. J. G. Truax, New York; Merchants' Exchange National Bank, New York; Dr. Henry H. Smith, Philadelphia; Dr. James Grundy, Macleod, Pa.; Dr. R. J. ORIGINAL ARTICLES.

SOME OF THE GRAVER AND RARER  
FORMS OF CINCHONISM.

*Read in the Section of Medicine at the Fortieth Annual Meeting of  
the American Medical Association, June 25, 1889.*

BY I. E. ATKINSON, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF  
CLINICAL MEDICINE IN THE UNIVERSITY OF MARYLAND.

Although everyone knows that the preparations and alkaloids of cinchona bark occasionally produce very undesirable effects upon the human organism, there seems to be a widespread impression that results of a more serious character are not to be apprehended, and one is accustomed to see these preparations administered with utter recklessness. It is true, the unpleasant results observed are usually the outcome of idiosyncrasy, and are not part of the regular physiological action of cinchona. As ordinarily observed this action cannot be said to be toxic in the sense in which we speak of the toxic action of strychnine, of opium, of arsenic, and the other well-recognized poisons. We regard as exceptional the various cutaneous disorders, the disturbances of the digestive, the respiratory, the circulatory and nervous systems not infrequently observed, and usually hold them to be accidental expressions of the resentment of the economy at the presence of the drug, expressions of idiosyncrasy. Although graver forms of quinine intoxication may very often be considered as due to the peculiar susceptibility of the individual, it is certain that in excessively large doses definite, dangerous, and even fatal poisoning may follow. Beyond the limits of physiological action there is an indefinite area in which idiosyncrasy appears to determine the toxicity, in which there can be no *a priori* determination of the danger line. While there is but slight danger to life from any but inordinate doses, quantities but little beyond the limits of everyday administration are capable of entailing grave consequences. These graver effects of cinchonism present but few terrors to the general medical mind, and when considered in relation to the universal employment of cinchona preparations in medicine are indeed numerically insignificant, yet research shows that our literature

abounds in indubitable evidence that their absolute frequency is by no means small. That the general medical public has failed to properly appreciate these dangers is largely attributable to the fact that many of the most important and intelligently reported observations have appeared in special journals.

Recent observation of disastrous results of cinchonism has prompted the writer to attempt to lay before this Association a brief *résumé* of a portion of the subject; and in bringing it before a body of general practitioners, he hopes to be pardoned for having presented in abstract and quite inadequately, a number of reports prepared with distinguished ability and with such minuteness of detail, that their exhaustive consideration can only be appropriately attempted by the specialist.

QUININE BLINDNESS.

*Case 1.*—On August 31, 1888, I was called to the country to see, in consultation, a young lady, 13 years of age, who had spent two weeks during the early part of the month at Atlantic City. She returned home on August 13th, not feeling well. She continued ill and on the 19th had a slight chill and took to her bed. She was visited by her physician who, finding her temperature to be 104° F., gave her sulphate of quinine in large doses, but without controlling the fever. The dose was gradually increased until she was taking 45 grains daily. She did not appear to be profoundly cinchonized; tinnitus was not very marked and deafness was slight. Her sight, however, began to fail and by the 27th she had become totally blind. The administration of quinine was not abandoned, and on the 30th she took three 10-grain doses. During this period the temperature ranged from 102° to 105° F., and the symptoms of typhoid fever became established. At the date of my visit she complained of slight pain in the occipital region. Her eyes were staring and her pupils widely dilated and quite irresponsive to light. There was a constant snapping of the lids, which the patient declared she could not control. There was complete blindness. She was not sensitive to the strongest light. No more quinine was given and the typhoid fever pursued a favorable course. On September 24th the blind-

ness was still complete, but by October 9th she was able to distinguish objects about the room, but with a field of vision still extremely limited. Dr. Russell Murdoch saw her on September 14th, and has kindly informed me, from his note book, that he found that "the arteries and veins were extremely reduced. There was entire loss of sight, both eyes being equally affected." On October 30th, after general tonic treatment and the use of strychnine, Dr. Murdoch found that the vessels had been restored to their usual size and the vision to  $\frac{xx}{20}$ , the field of vision alone remaining very slightly contracted.

Although the power of quinine to produce blindness in certain susceptible individuals, when given in excessive doses, has long been known, the fact has attracted surprisingly little attention until quite recently. As early as 1841 Giacomini<sup>1</sup> had observed quinine amaurosis. His case was as follows:

*Case 2.*—A man took from 12 to 15 grams (180 to 225 grains) of sulphate of quinine at a single dose. Within an hour he was seized with cardialgia, nausea, vertigo, incapacity of movement, and unconsciousness. Eight hours afterward there was subnormal temperature, cold extremities, livid lips and fingers, fetid breath, slow respiration, regular but very feeble pulse, inaudible voice, very dilated pupils, with sight and hearing almost gone. Recovery from this condition took place very slowly.

*Case 3.*—(Lewis, 1845.)<sup>2</sup> This was a case of total blindness occurring during the administration of large doses of sulphate of quinine.

*Cases 4, 5 and 6.*—(McLean, 1846.)<sup>3</sup> In one case about 16 grains of sulphate of quinine were given hourly until nearly an ounce had been taken. Another patient took 3 grains hourly for three days, and the third had 3 drachms in 6-grain doses within thirty-six hours. In all perfect blindness was the result. Amendment was slow, and recovery was perfect in none. One patient for nearly a year could look steadily toward the sun without seeing it. When he began to see sufficiently to read he would perceive a small luminous spot upon the paper about one inch in diameter, outside of which all was cloudiness and confusion.

*Case 7.*—(Baldwin.)<sup>4</sup> A negro girl, 6 years old, was given 28 grains of sulphate of quinine in forty-eight hours, for a tertian remittent fever. Shortly after the last dose the skin became dry and restlessness became very pronounced. Convulsions followed. The pupils became dilated and total blindness ensued. She was able to answer questions. Two hours later, with blind-

ness and dilated pupils, and restlessness, she died.

*Case 8.*—(Baldwin, *ibid.*) An adult male, with pneumonia, took 68 grains of sulphate of quinine in twenty and a half hours. One and a half hours after the last dose had been taken Baldwin saw him. A little while previously he had been seized with a jerking motion of the whole body. This lasted several minutes, and immediately afterward his vision was so imperfect that he could scarcely distinguish anything. There was great restlessness, anxiety and alarm. The pupils were dilated. Convulsive movements of the body came on every ten or twelve minutes, sometimes apparently of the whole body, sometime confined to the arms. During these convulsions he was not insensible—occasionally the eyes presented a vacant, staring look, with upward rolling. Three hours after the ingestion of the last dose of quinine he was completely blind. Vision began to improve in twenty-four hours afterward, but was never perfectly recovered.

*Case 9.*—(Trousseau.)<sup>5</sup> A patient in whom a dose of 48 grains of sulphate of quinine had caused temporary blindness and deafness.

*Cases 10 and 11.*—(Guersant.)<sup>6</sup> Mme. Bazire, being seized with malarial fever, was given by her husband, a physician, in a very short space of time 240 grains of sulphate of quinine. Soon afterward, her symptoms becoming more grave, she was given, at one dose, 375 grains. Dr. B. now fell sick himself, and no more of the drug was administered to her, but within a short space of time he administered to himself, by mouth and rectum, 900 grains, and took in eight or nine days 5 ounces. Reveillon found him covered with cold-sweat, completely deaf and blind, with slow and difficult respiration, and in a profound stupor, with the physiognomy of a drunken man. In this condition he died. Mme. B. recovered imperfectly, having been for a long time blind and deaf. The senses of sight and hearing always remained feeble.

*Cases 12, 13, 14 and 15.*—(Briquet.)<sup>7</sup> These were four patients who had taken from 45 to 75 grains of sulphate of quinine daily for several days. Twice the blindness was transitory, lasting only a day, and then completely disappeared. In the third case the blindness lasted longer, and in the fourth case it only disappeared after a month. (Briquet also quotes Monneret as having seen four cases of temporary weakening of the sight, in two lasting only a few hours, in one a day, and in one four days. He also quotes Hatin as having seen a case of quinine amaurosis which lasted several months).

*Case 16.*—(von Graefe.)<sup>8</sup> A patient took 6

drachms of quinine within two weeks. There resulted, violent tinnitus, deafness, moderate amblyopia in the left eye, and almost total blindness in the right eye. Four months later amblyopia of the right eye still existed. The visual fields and ophthalmoscopic condition in both eyes was normal.

*Case 17.*—(von Graefe.) A man took 15 grains of sulphate of quinine daily until almost one ounce was taken. When he increased the dose to 22 grains he had tinnitus aurium, hardness of hearing and weakness of sight, which increased in a few days to total blindness. Three months later blindness of the right eye was still complete. The sight of left eye was restored. Ophthalmoscopic condition and visual fields in both of these cases was normal.

*Case 18.*—(Voorhies.)<sup>9</sup> A young lady had taken within a few hours one ounce of sulphate of quinine, and one ounce additionally each day for the two succeeding days. On the morning of the second day she was extremely prostrate, hardly able to move her fingers. She had feeble pulse and hardly comprehended the simplest question. Audition was but slightly impaired, but she was perfectly blind. There was marked pallor of her face and of the palpebral conjunctivæ. The pupils were normal, responding promptly to light. There was anæsthesia of the cornea. The ophthalmoscopic examination revealed perfectly white discs. There was not a trace of the optic nerve vessels, veins or arteries. The choroidal vessels were empty. There was a pale, yellowish tinge of the retina. The treatment with amyl nitrite and quinine was not followed by improvement until the middle of the tenth week. The return of sight proceeded slowly until she was able to read Jaeger No. 1. More than a year afterward the optic discs remained perfectly white, with no trace of the central artery, except a small twig of that of the left eye, which was barely perceptible. The field of vision was greatly contracted, the greatest diameter (vertical) being less than 4" when taken at a distance of 2 feet.

*Case 19.*—(De Wecker.)<sup>10</sup> A man took a large but indeterminate dose of quinine. He awoke perfectly deaf and blind. Eventually he recovered his sight and hearing, the former imperfectly. The accident occurred in the tropics and some time must have elapsed before De Wecker saw him.

*Case 20.*—(Solomon.)<sup>11</sup> A seafaring man, 30 years old, took a teaspoonful of quinine at one dose. There soon followed vertigo, chilliness, a sense of sickness and failure of sight. After some interval Solomon found that he could read brilliant type (Jaeger's No. 1), a single letter

only at a time, so contracted was his field of vision, so complete was the anæsthesia of the retina, except at the point occupied by the yellow spot. The pupils were of normal diameter but moved sluggishly. The symptoms gradually subsided, and nine months afterwards the patient declared himself to be in perfect health.

*Case 21.*—(Roosa.)<sup>12</sup> The patient was a man who began to take compound tincture of cinchona to remove the cravings of the alcohol habit. He was 50 years old. On June 24th, 25th, 26th, 27th and 28th he continued to take this preparation in doses of from one to two ounces at short intervals. During these days he drank a quantity representing 125 grains of an alkaloid of cinchona. Two days later (July 1) he was stupid, with flushed face and conjunctivæ, and was apparently unable to see or hear. On July 3d hearing had become almost normal, but his sight remained much impaired. Vision: R. E. = quantitative perception of light. L. E. Could count fingers at a distance of one foot. The ophthalmoscope revealed lessened size of the arterial vessels, there was no abnormality in the veins, there was a lessened number of vessels on the papillæ, but no marked paleness. There were no changes in the membrana tympani. Strychnine was ordered. On July 6th he was able to walk about. Vision: =  $\frac{2}{30}$  in each eye, but the visual field was very much contracted. July 16th. Both visual fields were concentrically limited. Measurements drawn on a blackboard 14" distant were: Rt. field, vertical 9", horizontal 7½"; limitation most marked on the temporal side. Left field, vertical 7", horizontal 8", limitation more regular. Optic papulæ very pale and arteries narrow. July 20th. Vision: =  $\frac{2}{30}$  in each eye. Can see perfectly well in a straight line, but when walking about a room has some difficulty in seeing small articles of furniture. On April 23, 1879, his condition was substantially the same. The visual field was increased somewhat in the left eye, = 9" vertically and 16" horizontally. The optic discs remained pale and the arteries small. There were no other ophthalmoscopic changes.

*Case 22.*—(Roosa and Ely.)<sup>13</sup> Mrs. B., 34 years old, was seen Nov. 7, 1879. She had pernicious malarial fever in Cuba in Nov., 1877. During one day she took 50 grs. of sulphate of quinine, during the next day 90 grs., and during the three or four succeeding days 30 or 40 grs. At 11 P.M. of the day upon which she took 90 grs. she became blind and remained so for three or four days. After that a gradual restoration of sight occurred. There were no aural symptoms. Her intellect remained clear most of the time. The blindness was so complete that she had no perception of light.

<sup>13</sup>Archives of Ophthal., Vol. ix, 1880, p. 41.

Vision was perfect before her illness, but had never been so good since. She felt as if there were a veil over her eyes and was unable to tell whether her linen was clean when it came from the wash. She could not see certain shades of dark blue well, but distinguished all other colors imperfectly; she had most difficulty with red. When her vision first began to return she had no color perception whatever. R. E. Vision =  $\frac{2}{3}$ ; reads 1 Jaeger fluently. L. E. Vision =  $\frac{2}{3}$ ; reads 1 Jaeger fluently. V. =  $\frac{2}{3}$  with both eyes open. The fundus of each eye was somewhat indistinct; the discs were too white; the capillaries seemed deficient. The visual fields as tested at 12" by Carmalt's perimeter were concentrically limited.

Case 23.—(Gruening.)<sup>14</sup> A woman, 35 years old, had a miscarriage at the sixth week. Septic symptoms succeeded. She was given 80 grs. of sulphate of quinine in thirty hours. Shortly after the last dose she had convulsions characterized by twitchings of the facial muscles and jerking of the upper and lower extremities. She did not lose consciousness during this attack. When this had passed she was totally deaf and blind. Her hearing returned in twenty-four hours. Gruening found the pupils dilated *ad maximum*, without either direct or consensual contraction. Accommodative contraction was clearly demonstrable when the patient made a strong convergent effort. Both refractive media were clear. The optic discs were pale and transparent, with well defined outlines. The retinal arteries and veins were so attenuated that in the inverted image they could hardly be perceived. In the upright image the vessels appeared as continuous, exceedingly narrow bands tapering to fine points somewhat abruptly. The slightest pressure upon the eyeballs made all the vessels bloodless. At the macula of each eye there was a cherry-colored spot surrounded by a zone of bluish-gray opacity. Blindness was absolute—the light of an Argand lamp concentrated upon the eye by means of a convex lens was not perceived. There was no phosphene by pressure. The galvanic current elicited no reaction of the optic nerve. There was no pain. Hearing was blunted. The tympanic membrane was not injected; there was no albuminuria. Eight days after the occurrence of blindness Knapp saw the case and agreed in the diagnosis of quinine amaurosis. At that time the circumvascular retinal opacity and the cherry-colored spot at the macula had disappeared; the optic discs and the retinal vessels remained unchanged. The pupils were moderately dilated and fixed except with efforts of convergence, when slight contraction was noticeable. July 19 (twenty-second day) she could discern the position of the window. She had quantitative perception of light in both eyes. After losing and regaining perception of light more than once she was finally (August 16, about seven

weeks after the attack), able to count fingers with either eye at a distance of 4 feet. August 30 she read ordinary type with + 3 D., her hypermetropia being 3 D. The letters, however, appeared white upon a black ground. She was totally color blind. On September 23 the pupils were moderately dilated without any direct or consensual action, but contracted with accommodating efforts. Refractive media clear. The optic discs were still very pale but transparent. The retinal veins and arteries were filiform, with + 3 D.; her sight was  $\frac{2}{3}$  and she read Snellen 1½ with either eye. Field of vision concentrically limited; that of the right eye measured 30° on the temporal side but did not extend to 20° in any other direction; the left eye vision was still more contracted, extending to about 18° on the temporal side, less than that in all other directions. On Snellen's color chart she recognized no color. All the letters appeared gray to her, but the yellow ones were much lighter than the others. In the spectroscope she saw only a number of gray stripes of different shades. November 8. The field of vision slightly enlarged and color sense improved. December 28, 1880, she was able to distinguish the four fundamental colors, yellow, blue, red and green; the two latter, however, only when presented in large surfaces. The fields of vision were increased.

Case 24.—(Buller.)<sup>15</sup> A woman, 34 years old, had recently been confined. Septicæmic symptoms appearing, she was given two doses of sulphate of quinine, of 20 grs. each, during the first twenty-four hours, the same doses on the second, and on the third day she took three doses of 20 grs. each. On the following day fever and delirium were gone, but she was absolutely blind. Buller saw her during this day (August 27, 1879). Externally, the eyes appeared normal. The tension and movements were natural, the pupils were widely dilated and not responsive to the strongest illumination, nor to the effort of accommodation. The refractive media were normal. Left eye. There was a diffuse, bluish-gray haziness or turbidity of the retina for a considerable distance in every direction, most markedly in the region of the macula, the centre of which, by the direct method, had the appearance of a cherry red patch about 1 line in diameter. There were no retinal hæmorrhages and no choroidal changes. The retinal veins as compared with the retinal arteries were unusually large, but decidedly paler than in healthy eyes. The arteries were normal except actually or relatively diminished in size. Arterial pulsation was readily evoked by pressure upon the sclerotics. The opacity of the retina nowhere obscured the vessels, and the small branches converging toward the macula were unduly conspicuous. The retinal cloudiness gradually faded toward the periphery. *Right eye.* The

<sup>14</sup> Archives of Ophthal., Vol. x, 1881, p. 91.

<sup>15</sup> Trans. Amer. Ophthal. Sec., 1881, p. 262.

same changes were present, though to a less degree. By 5 P.M. of August 29 (second day) she was able to distinguish bars of light through the Venetian shutters. September 1 (fifth day), at a distance of 15 feet vision was clear over a surface 1 foot in diameter and indistinct over an area of  $2\frac{1}{2}$  feet. She could tell blue and red letters in a motto across the room. On the seventh day she could distinguish all colors in a subdued light, but for the first time there was noted a marked diminution in the calibre of the retinal vessels. The condition looked like one of moderately advanced atrophy. September 4. The retinal vessels were not half their normal size. The cornea was not anæsthetic. September 6. Read Jaeger 8 easily without glasses. November 1. At a distance of 14" the vision of the left eye was: upward 8", downward  $9\frac{1}{2}$ ", inward 8" outward 12". Vision =  $\frac{2}{30}$ . She could distinguish all colors, at the centre only. After an interval of twenty-two months, there was a total abolition of all sense of color except central color perception, which was perfect. Central vision was perfect. The nerves were both pale but not white. The arteries and veins were not more than one-third as large as normal. The arteries could not be traced as far as the ophthalmoscopic border and some of them had white bands for a short distance. Some of the veins, however, were not lost. Subjective sensations of light and after-images that were formerly quite troublesome were now only occasionally noticed. Buller assumed that the final changes had now been reached.

Case 25.—(Webster.)<sup>16</sup> A man, 23 years old, had taken, seven years previously, during the course of a night, half a dozen large doses of sulphate of quinine. The next morning he was totally blind. He remained thus only a few hours, but he had never seen so well since. Vision, right eye, =  $\frac{2}{30}$ , with +  $\frac{1}{4}$  C., axis  $90^\circ$ . Vision, left eye, =  $\frac{2}{40}$ ; not improved by glasses. Ophthalmoscopic examination. Except that there were whitish bands running along the borders of the nasal branches of the left central retinal vein and that the optic disc of the same eye was slightly paler than it should be, both eyes were normal.

Case 26.—(Webster.)<sup>17</sup> A lady, 40 years old, after frequent attacks of cholera morbus, had a very severe seizure of the same malady on July 25. Quinine was given *per rectum* until she had received 105 grs. (in doses at intervals of three hours). Next day its use was resumed, she was given 5 gr. doses every third hour up to 25 grs. whenever there seemed to be signs of the return of a chill. (She had also taken, as a tonic, 5 grs. of quinine daily ever since until January 13.) On the third day of her attack she became aware that she was blind and very deaf. Her hearing returned in a few days. The return of vision was gradual, but

it remained extremely imperfect. January 13, she could see a circle of light about a yard in diameter when she looked at a lighted lamp, or saw as if the light were shining through a thick fog. At first she only saw through the extreme outer corners of the eyes and not at all in front. Now, objects seen on either side were dark, while those in front were still outlines of golden light. Present condition. Right eye =  $\frac{2}{200}$ ; left eye =  $\frac{1}{100}$ . The discs were perfectly white and the arteries were entirely obliterated and replaced by white lines. The very few minute retinal arteries had white lines along their sides. There were a few white, fleecy looking connective tissue changes in the retina near the disc and a mottled condition of the choroid. The pupils dilated downward and outward nearly symmetrically and there were deposits on the anterior capsules of the lens. She derived no benefit from treatment.

Case 27.—(Michel.)<sup>18</sup> A man, 38 years old, took in twenty-four hours 40 grs. of sulphate of quinine. During the next twenty-four hours he took 50 grs. Then during the following night he took 220 grs. in powder. Part of this was not retained. Suddenly, at midnight, without pain, his vision became totally extinct, "just as if you had blown out a lamp." Deafness was not absolute. It lasted ten days, but he never regained his previous acuity of hearing. Four weeks later both pupils were widely dilated. Neither the strongest light nor sulphate of atropine affected them in the smallest degree. The optic discs were white with a slight tinge; the inner third (inverted image) somewhat darker in hue. Scleral rings were very marked. The *arteriæ centrales* were barely visible as minute threads, not traceable far from the origin of the disc. The veins were less than one-half their normal size. The choroids were pale. March 9 (five weeks), the arteries and veins were slightly increased in size and color. The patient thought he could perceive a slight glimpse of light. March 21, the retinal vessels were even more threadlike than at any time since first seen. By the following August (six months), he noticed that in certain positions he could perceive varying degrees of light. By the middle of October he was able to roughly locate an object held up before him. By November 1 he could read words in a newspaper. Since then the patient thought there had been no improvement. February 14, vision R. E. =  $\frac{1}{2}$ ; L. E. =  $\frac{1}{2}$ . Both eyes together =  $\frac{1}{2}$  imperfectly. Field of vision, tested at 1 metre: Right, in vertical diameter, = 23 cm.; right, in horizontal diameter, = 29 cm. Left, in vertical diameter, = 18 cm.; left, in horizontal diameter, = 24 cm. Pupils in the strongest light = 4 mm.; pupils in ordinary light = 5 mm. They responded slowly. Ophthalmoscopic examination: All of the retinal vessels had increased in calibre; the

<sup>16</sup> Archives of Medicine, Vol. x, 1883, p. 338.

<sup>17</sup> Archives of Medicine, Vol. x, 1883.

<sup>18</sup> Archives of Ophthalmol., Vol. x, p. 214.

arteries were about one-third their normal size; the veins about one-half. The arteries could be followed two-thirds of their normal course. March 9, the field of vision was improved in both eyes. May 5, the field of vision unchanged in right eye, apparently a little less in left eye. Tested with Galezowski's *échelle chromatique*, he saw no color in grade No. 1 (No. 1 consists of very light shades of red, yellow, green and blue). In grade No 5, red and yellow were easily distinguished, blue with some difficulty, green not at all; violet looked like "dirty white." In grade No. 10, red, yellow and blue were promptly distinguished; violet was called purple; green looked like a mixture of green and yellow. In grade No. 15, red, yellow and blue were quickly recognized; green was not seen. (He acknowledged that before his blindness he did not know colors well.) June 1 (sixteen months). The field of vision was unchanged, likewise the size of the pupils, but they responded promptly to light. No changes were observed in the fundus of the eyes.

*Case 28.*—(Banngarten. Reported at the same meeting at which Michel's case was related.)<sup>19</sup> A boy, after taking what was estimated to be about 5 drachms of quinine, lost sight and hearing. He recovered in about six weeks.

*Case 29.*—(Knapp.)<sup>20</sup> A girl, 7 years old, had been treated for malaria three months previously and had taken a great deal of quinine. On the sixth day she became hard of hearing, and for four days could see nothing and the pupils were immovable. On the tenth day she saw fire in the grate. Improvement had been slow, and she continued to have weak sight, and she felt uncertain in walking. When Knapp saw her she could easily read Snellen xx at 20', and 0.25 at 8" with each eye, with moderate concentric limitation of visual fields. Color perception was normal. Both optic discs were white, the retinal vessels scant and very small, especially the arteries (February 16, 1878). May 11, 1879. Four months previously she again took quinine for malaria; no more, however, than 10 grs. in one day. From that time her sight was impaired. Knapp found S.  $\frac{2}{100}$  in the right and  $\frac{2}{100}$  in the left eye. She read 0.50 with difficulty, no improvement with glasses. She was green-blind. Field of vision was very much contracted; in the right eye almost to the point of fixation, in the left having a diameter of 15°, of which 5° were on the nasal, 10° were on the temporal side, from the point of fixation. The optic discs were white; the blood-vessels, especially the arteries, few and small. Now referred the disturbance to the influence of quinine. In May, 1881, her sight was  $\frac{3}{100}$  in each eye. Emmetropia. She experienced no inconvenience from her eyes in any way. Her perception of color, carefully tested, was perfect. Her

light sense was normal; her field of vision, however, was contracted. The optic discs were white, with a faint pinkish tinge. Both arteries and veins were few and small, but none were white. The choroidal vessels, clearly visible, were normal in color, size and distribution. Otherwise the appearance of the *fundus oculi* was normal.

*Case 30.*—(Knapp.)<sup>21</sup> A boy, 17 years old, had had "a terrible malarial fever from sewer-gas," four years previously. He was ill two weeks. After the first day he took large doses of quinine every third hour for a whole week. In the second week he took one large dose every day before the attack. The pupils dilated. On the tenth day he did not see anything; later, he gradually and very slowly recovered his sight, but he has been awkward and stumbling ever since. For two and one-half years nystagmus had been noted. Condition on examination: "Vertical vibratory nystagmus. Periodic divergence of the right eye; pupils move well. Optic discs white; vessels very small, some converted into white cords. V. R.  $\frac{2}{100}$ ; L.  $\frac{2}{100}$ . Recognizes colors correctly. Field of vision in both eyes concentrically contracted; in the right eye to a diameter of 20°; in the left eye, of 30°.

*Case 31.*—(Knapp.)<sup>22</sup> A boy, 8½ years old, had cerebro-spinal meningitis when in his third year (mother's statement). He was brother to the preceding case. He took a great deal of quinine. When he came out of his stupor at the end of two weeks, he could not see anything, not even a bright light held before his eyes. After some weeks he began to see a bright light and very slowly recovered his sight, his eyes remaining weak for some years. When Knapp saw him, December 18, 1880, his optic nerves were pale, the left more so than the right; atrophic-looking. The retinal blood-vessels were abnormally small. He was myopic and read with —  $\frac{1}{18}$  Sn. lxx at 20', and 0.50 near by, with each eye. Visual fields were moderately contracted and had the shape of a horizontal ellipse. June 8, 1881. Light sense normal; color sense carefully tested proved normal too, but he had some difficulty in recognizing contrast shadows and called the yellow shadow from a blue glass, brown.

*Case 32.*—(Saunders.)<sup>23</sup> A boy, 8 years old, who had been healthy previously, was taken ill September 15, with fever and vomiting. On the 16th he was ordered to take a 6 gr. capsule of quinine every second hour. The third capsule was rejected. No more was given until the next day, when he took doses of 12 grs. every second hour until three doses had been given; then, the stomach becoming irritable, 20 grs. were given by enema. The quinine was now withheld until midnight of the 17th, when 10 grs. were given by the mouth, but were rejected. This dose was

<sup>19</sup> St. Louis Courier Med., November, 1880.

<sup>23</sup> Mississippi Valley Med. Monthly, No. 11, 1882, p. 433.

repeated and, after its partial rejection, 20 grs. were given by enema. This was partially thrown off and 20 grs. more were administered by enema at 4 A.M. (The patient had been quite deaf for the past twenty-four hours. He had taken more than 100 grs. in three days.) Shortly after this hour he became more deaf and stupid and difficult to arouse. His respiration was labored and quite slow, only 4 or 5 per minute. His attendants becoming alarmed, active efforts at resuscitation were practiced, and he rallied in about one hour, but he was totally blind, not able to distinguish light from darkness. Deafness lasted thirty-six hours; blindness four days. Saunders also refers to three other cases of quinine amaurosis as having occurred in the neighborhood of Memphis during the past few years.

*Case 33.*—(O'Bryen.)<sup>24</sup> A man, æt. 33 years, had high fever. A ship's surgeon attempted to reduce it by giving quinine; this was taken in doses of 25 or 30 grs. every second hour (January 6). On January 7, the patient noticed buzzing, deafness, dimness of vision and finally total blindness. On March 20, he remained totally blind. His pupils were widely dilated. There was no albuminuria. About twenty days later he was able to perceive a blue and white handkerchief at a distance of about 3 feet. At a later report, sight appeared to be slowly but steadily improving.

*Case 34.*—(Dewey.)<sup>25</sup> A man, 22 years old, was seized with pneumonia. There was a prolonged cold stage, lasting some hours, during which his physician gave him  $\frac{1}{2}$  oz. of sulphate of quinine in divided doses. A good deal of this was rejected by vomiting. In less than twelve hours he was totally blind and deaf. The deafness entirely disappeared in seven or eight days, but the blindness remained. After three months he could hardly distinguish night from day. His sight gradually improved, and at the end of eighteen months he was able to go about his farm and to attend to business a little.

*Case 35.*—(Bruns.)<sup>26</sup> A young man, 24 years old, suffering from malarial coma, was given 480 grs. of sulphate of quinine within twenty-four hours. There was a sudden reduction of vision to light perception. The further course was not reported.

*Case 36.*—(Roosa.)<sup>27</sup> Mrs. L. took for malarial coma, 30 gr. doses of sulphate of quinine, *per rectum* two or three times. Consciousness was restored upon the third day, when she was found to be unable to distinguish light from darkness. The pupils were dilated and the ocular conjunctiva greatly congested. For some time there was no improvement, and when recovery began, it was slow. After six weeks she could not see to walk alone but could distinguish, with difficulty, col-

ored objects in the room. She could count fingers 4 feet distant, but could not make out a letter. The ophthalmoscopic appearance were those usually seen in similar cases. Under the hypodermic use of strychnine there was much improvement. This patient had marked nystagmus and eccentric vision.

*Case 37.*—(Gruening.)<sup>28</sup> A lady, 50 years old, took 30 grains of quinine on account of malarial intoxication. On the following morning she awoke blind and deaf. The deafness lasted until the evening and the blindness began to disappear the succeeding morning. Five days afterward she had a perfectly healthy fundus in each eye. Central vision was normal, but the fields were much contracted, not more than 30° in any diameter.

*Case 38.*—(Diez.)<sup>29</sup> A boy, 6 years old, suffering from chronic malarial poisoning, took heavy doses of quinine. As the fever disappeared there developed divergent strabismus, more pronounced in the right eye. There was also exaggerated dilatation of the pupils. Vision in each eye diminished more and more until he could hardly distinguish light from darkness. The ophthalmoscopic examination showed perfect transparency of the refracting media. The optic nerve papillæ were pale and the retinal vessels very much contracted. Under treatment with strychnine there was very decided improvement during the thirty days he was under observation.

*Case 39.*—(Peschl.)<sup>30</sup> A woman, 28 years old, had taken from 45 to 60 grains of quinine in six days. There developed suddenly symptoms of cinchonism, especially blindness and deafness. The former symptom lasted only several hours, the latter, two days. Five days afterwards central vision for colors had not returned. The field of vision was much restricted. There was extreme ischæmia of the fundus of the eyes. The papillæ were pallid, but circumscribed. There was slow but continuous improvement. Color perception returned, but fields of vision remained very limited. Nine months later the visual power was normal, but the field of vision for colors notably restricted. The fundus remained very anæmic, the arteries were accompanied by white streaks.

*Case 40.*—(Hobby.)<sup>31</sup> A young lady, 21 years old, had taken large doses of quinine for supra-orbital neuralgia. When seen by Hobby the right eye was apparently normal. The pupil of the left eye was widely dilated and not appreciably affected by light. The ophthalmoscope revealed intense ischæmia of both retinæ. O.D.S. =  $\frac{16}{xxxii}$ ; O.S.S. =  $\frac{3}{cc}$ . There was improvement under treatment, but the neuralgia becoming

<sup>31</sup> Archives of Ophthalmol., 1882, Vol. xi, p. 34.

severe and markedly periodical she was given 20 grains of sulphate of quinine in two doses one hour apart. Upon the fourth day following this she returned to Hobby with both pupils dilated to the utmost.  $O. D. S. = \frac{16}{cc.}$ ;  $O. S. S. = \frac{3}{cc.}$ . The visual field was reduced to one-tenth of the normal. Both retinae were profoundly ischaemic. Quinine amaurosis recognized and strychnine administered hypodermically. There was rapid improvement; in ten days the acuteness of vision had returned to  $\frac{16}{xx}$  in both eyes; the visual field in each had doubled. Six weeks later the visual acuteness remained unchanged. The visual field had increased but was still less than half the normal.

*Case 41.*—(Nettleship.)<sup>32</sup> A man, 26 years old, who had been ill with fever in Western Africa toward the end of Summer. Before leaving the Coast or during the early part of the voyage he took 7½ grains of sulphate of quinine, in divided doses, daily, for two days, and on the third day he took the same amount in a single dose. His sight rapidly became dim during this day, so that he could neither read nor see distant objects clearly. He took no more quinine. His sight improved, but had not entirely recovered when Nettleship saw him, three weeks later. He informed N. that two years previously he had dimness of vision for a single day while taking quinine.

*Case 42.*—(Nettleship.)<sup>33</sup> A man, 29 years old, had had Congo fever in June (22d). For this he took immense doses of quinine. Three days later he discovered that his sight was very bad. He quickly recovered from his fever and started for home. By July 3d he was able to read. Nettleship saw him August 19th. Visual acuteness was nearly normal. There was very marked contraction of the field for colors, especially for red and green, the color, as a rule, being only recognized when close to the center. Though vision was almost perfect it was not quite so in bright light, and early in the morning he saw everything as through a mist. The optic discs were rather pale all over and the neighboring parts of the retina slightly hazy. The arteries were decidedly diminished, the veins normal.

*Case 43.*—(Doyle.)<sup>34</sup> A patient, in whom blindness supervened in the night while he was taking large doses of quinine. The arteries were contracted to mere threads and scarcely conveyed blood beyond the disc. Complete blindness lasted for several days. Vision was slowly recovered, but the fields of vision were still very contracted. Though the accident had occurred several months previously the arteries remained contracted and the discs were still whitened.

*Case 44.*—(Dickinson.)<sup>35</sup> A boy, 10 years old, had ague, August 3d, 5th and 7th. During the intervals his father gave him about 30 grains of sulphate of quinine. On the 11th he complained of feeble vision and darkness. On the 13th vision was so diminished that he could hardly see to eat. His vision continued to decline and in a day or two he lost all perception of objects, and even of the light of day. Occasionally he perceived flashes of red light and had pain in the occiput. This extended forward on each side to the external canthus. There was also pain in the neck and back. When Dickinson saw him, August 22d, he was totally blind. The external appearance of the eyes was normal. The pupils were dilated and not responsive to light. All dioptric media were intact and transparent, but there was marked congestion of the retinal and choroidal vessels, together with a remarkable tumefaction of the optic disc, it appearing swollen and pushed forward prominently with the vitreous. Its condition was very similar to that denominated "staunungs papille," "choked disc," the usual concomitant or resultant of neuroretinitis. A stasis of blood had been occasioned, in which the lamina cribrosa had especially participated. Under treatment, quite good vision had been regained in ten days, and two weeks later advices were very encouraging. Vision returned first in the right eye, which had also been the first to be affected. It was stated that the boy's mother had had a similar experience.

*Case 45.*—(Browne.)<sup>36</sup> A powerful man, 34 years old, who had had syphilis in 1877, was seized with pneumonia on January 4th. On January 6th, his temperature being 104° F., he was ordered to take 10 grains of sulphate of quinine every sixth hour. January 9th, temperature 105 F., the dose of quinine was increased to 30 grains every second hour. He thought he took about 120 grains. On the afternoon of the 7th he became deaf, and remained so about twenty-four hours. About 4 P.M. there was a flickering before his eyes and his sight went, "exactly as if you had turned out the gas." He could tell the difference between sunlight and darkness by the periphery of the left retina. Centrally he could not do this. The pupils were widely dilated. He could not see the flame of a candle. Six weeks after his attack his sight began to return. Recovery for central vision was rapid. March 24th Messrs. Power and Vernon saw him at St. Bartholomew's Hospital. Both optic discs were white, the vessels small and contracted. The left pupil was slightly the larger. Both acted slowly to light and to accommodation. Vision: Right eye =  $\frac{5}{8}$  Sn. 1½. All colors had a dirty, faded look. Left eye,  $\frac{5}{8}$  Sn. 1½. He named and matched colors pretty correctly. The fields were much con-

<sup>36</sup> Transact. Ophthal. Soc. United Kingdom, Vol. vii, p. 193.

tracted. There was a small area of perception of white on the outer periphery of the left field. Field for color limited to the *fovea centralis*. Browne saw him on April 19th. Pupils  $3\frac{1}{2}$  mm., equal, acting to light and to accommodation. Central color vision quite perfect. Vision: R.  $\frac{2}{3}$   $\frac{2}{3}$  2; 1 Jaeger at 12" fluently. L.  $\frac{2}{3}$  5  $\frac{2}{3}$  2; 1 Jaeger at 12" fairly. Slight paresis of left internal rectus; optic discs pale; vessels remarkably small and contracted. There were no other changes in the fundus. Dec. 4th. There was scarcely any change, except slight failure of vision in the left eye. V.: R. =  $\frac{2}{3}$  6. L.  $\frac{2}{3}$  4. When reading 1 Jaeger with the left eye the letters danced (slight weakness of internal rectus?). The fields were unaltered. He could distinguish a light thrown from a small mirror up to the periphery of the retina. Very curious telescopic vision. Health was remarkably good.

Case 46.—Galezowski,<sup>37</sup> quoted by Browne.) Blindness occurred in a man who took 105 grains of quinine. It was complete. The patient could not see the sun. This lasted some days. Seven months afterward his vision =  $\frac{2}{3}$  — 2 J. difficult. During convalescence he had central scotomata for awhile. There was no contraction of the field. The optic discs were pale and the vessels very contracted.

Case 47.—(Championiere—quoted by Browne.) A woman who took from 45 to 60 grains of quinine became completely deaf and blind, and could only communicate by touch. She recovered both sight and hearing.

Case 48.—(E. Williams—quoted by Browne.) A man took one ounce of quinine in four days, and became totally blind and deaf. Both sight and hearing were restored in six weeks. Hearing was permanently impaired. The optic discs were white and the vessels small. The vessels were contracted concentrically.

Case 49.—(E. Williams—quoted by Browne.) A boy, 14 years old, who took a large dose of quinine. He was totally blind for four days. The optic discs were white. The visual fields were contracted.

Cases of amblyopia from the excessive use of quinine have also been reported by Nucl,<sup>38</sup> Hixson,<sup>39</sup> H. C. Wood,<sup>40</sup> who mentions that he has seen complete temporary amaurosis produced in a lady by 12 grains of quinine. The subject has also received attention from Lopez,<sup>41</sup> Masimiliano,<sup>42</sup> and a number of other writers. Blindness has likewise been noted, as will be shown later, among the symptoms of dangerous and fatal general poisoning by quinine.

In the (more than fifty) cases of quinine amaurosis of which I have found records, the blind-

ness was absolute in nearly all, but, unquestionably, if careful research were instituted it would be discovered that impaired vision is not at all an infrequent symptom of cinchonism. Rogers<sup>43</sup> has already called attention to this phase. He asserts that after the ingestion of 20 grains of sulphate of cinchonine the following phenomena may be pretty constantly observed: In about one hour there are cardiac weakness and irregularity, and much debility with tremor. Paresis of visual accommodation progresses to such an extent as to be almost complete in many instances at the end of the second hour; at this stage even the emmetropic eye will require the aid of a No. 10 convex glass to properly distinguish objects at the normal near point. This paresis, he says, lasts eight or ten hours. Probably the great majority of cases of incomplete quinine amaurosis escape observation and record. Briquet, who saw four such cases thus describes the evolution of the symptoms. Says this writer, the patient begins to complain of the light, and the effort to fix the eye upon objects is painful. There is a sensation like that produced by using strong glasses. The eye is brilliant. The pupils are usually normal and the conjunctiva not injected. There is, then, a slight degree of excitation of the optic nerve, analogous to that so often seen in the beginning of paralysis of the nerve. In a more advanced degree, patients see as through a mist. Objects seem small, or double, or are not perceived at a distance of 2 or 3 metres. Finally incomplete amaurosis may occur, when the pupils become dilated, insensible to light. Briquet quotes Monneret as also having seen four cases of this incomplete amaurosis. A number of the cases here presented in synopsis were examples of incomplete blindness. For instance, Bruns' case was one of sudden reduction to perception of light, so was that of Diaz. Nattleship had a case in which, after doses of  $7\frac{1}{2}$  grs. of quinine taken in two doses daily for two days and a similar dose taken on the third day, the sight rapidly became dim, reading became impossible and distant objects were seen indistinctly. This patient had two years previously had indistinctness of vision after taking quinine.<sup>44</sup> In most cases the blindness develops suddenly. More than once it has been described as occurring "just as if a lamp had been blown out." In many cases, however, vision fails much more gradually. Blindness generally becomes complete within twenty-four hours, though in some cases several days may elapse before this occurs. The duration of total blindness, the absence of all perception of light, varies within wide limits, from a few hours (Peschl, Webster, *et al*) or a day or more (Briquet, Baldwin, Buller, Gruening, *et al*) to several, even many, weeks (three, Gruening; five, Michel; ten, Voorhies; nearly

<sup>44</sup> Loc. cit.

three months, Dewey). In most cases perception of light returns within a few days. I can find no case recorded where blindness remained absolute. In all sight is recovered, though often slowly, and nearly always imperfectly. Six months after the beginning of blindness one of Gruening's cases was still partially color-blind and the fields of vision remained contracted. During the greater part of the first year one of McLean's patients "could look steadily at the sun without seeing it or even without any painful sensation being produced." In one of Roosa's cases the visual fields remained contracted, the optic discs pale, and the arteries small. In another the patient, whose vision was said to have been perfectly normal previously, felt, after two years, as if there had been a veil over her eyes, and she could not tell if her linen was clean as it came from the wash. She was also unable to distinguish certain shades of dark blue. In Voorhies patient the optic discs remained perfectly white after nearly a year, and there was no trace of the central artery, except a small twig. The visual field was greatly contracted. After an interval of twenty-two months, Buller found in his patient a total abolition of all sense of color, except by central perception. Central vision was perfect. The nerves were both pale, but not white. The arteries and veins were not one-third as large as normal. Webster reported a case, where, seven years after the beginning of blindness, which was total only a few hours, the sight remained impaired. Browne states that in one case the visual field remained contracted after fifteen years. In nearly every case where the condition of the sight was accurately determined some damage to vision remained when the patient was last observed. As regards peripheral vision the blindness remains permanent. Central vision gradually returns to the normal after some days, weeks or months (Gruening).

The exact nature of the eye affection has been carefully studied by Voorhies, Roosa and Ely, Gruening, Knapp, Buller, Webster, Michel, Browne and other ophthalmologists, and we are able to-day to recognize in quinine amaurosis a pretty well-defined symptom—complex. This is constituted by 1. Transitory blindness, complete or incomplete, usually developing suddenly. This blindness may be more complete than in any other recoverable condition, and is comparable to the blindness of atrophy (Browne). 2. Color-blindness. As sight begins to return most cases will be found to be color-blind, completely or partially. The color sense gradually returns and may ultimately become restored. In some cases the diminution of light sense is permanent. 3. Wide dilatation of the pupils. The pupils are irresponsive to light, but are said to respond to accommodative effort. It is to be inferred that the dilatation is due to the blindness, and that

there is no implication of the third or sympathetic nerves. 4. There is pallor of the optic discs and extreme diminution of the retinal vessels, both veins and arteries. In many cases this is permanent. In cases examined early by the ophthalmoscope, a whitish haze, with cherry-colored spots, has been observed at the maculae, as in cases of embolism (Browne, Buller, Gruening). 5. There is contraction of the visual field. This is extreme and expands slowly. There is no reliable evidence that it ever regains its normal extent. "The contraction is concentric or elliptical, with the longest axis in the horizontal direction." (Knapp.) Impairment of hearing (at times to total deafness) with *tinnitus* appears to be present almost invariably. It is rarely complete more than twenty-four hours and gradually disappears. Some variations from this type have been noted. Voorhies' patient had anaesthesia of cornea. Diez, Knapp and Browne observed divergent strabismus. One of Roosa's cases had marked nystagmus; likewise one of Knapp's. Dickinson noted in his patient "marked congestion of the retinal and choroidal vessels, together with a remarkable tumefaction of the optic disc, it appearing swollen and pushed forward prominently with the vitreous. Its condition was very similar to that denominated 'staunungs-papille,' 'choked disc,' the usual concomitant or resultant of neuro-retinitis." This is a striking variation from the, otherwise, universal experience, and it may not be impossible that the symptoms in this case were expressions of malarial intoxication, such as are occasionally observed.<sup>4</sup> Taken altogether the symptoms of quinine amaurosis are strikingly definite and constant. Knapp's first case appears to show that relapse may be excited by quite small doses. One of Nettleship's patients exhibited the predisposing idiosyncrasy in its extremest degree, his sight being seriously damaged by 23 grains of quinine administered during three days two years after he had been similarly affected by quinine.

The pathogenesis of quinine amaurosis is by no means understood. Browne remarks that the subjective symptoms and ophthalmoscopic appearances resemble those of embolism of the central artery or hæmorrhage into the optic nerve, but that the bilateral occurrence and complete recovery of central vision refute this theory. He considers the anaemia of the retina to be local and that the occlusion of the arteries is probably not retro-ocular and is not complete, or atrophy of the optic discs would have occurred, as it does after embolism. There is no sign of perineuritis. There is no pressure. Buller, who thinks that the seat of the morbid changes is the optic nerve between the chiasm and the eyeball, notes that a galvanic current applied to the optic nerve of a

<sup>4</sup> Ledda. Temporary Bilateral Amblyopia in Consequence of Malarial Poisoning. Lo Spallanzani, 1885, Vol. xiv, p. 201, *et al.*

rabbit will speedily induce a blanching of the retina and nerve similar to that which occurs in quinine blindness. He details an example where, by the same means, he accidentally produced a similar picture in the human eye. The needle, introduced back of the orbit, he thought, must have penetrated the optic nerve. After the application had lasted one and a half minutes the pupils became widely dilated and the patient averred she could not see. A few minutes later the vision in this eye was reduced to counting fingers at a distance of one foot. The retina whitened to the disc and macular region. The arteries were slightly reduced in calibre and the nerve was decidedly pale. The retina cleared up in a few days, but the optic nerve remained very much blanched and the arteries small. The diminution of vision, which finally settled down to  $\frac{2}{200}$ , appeared to be uniform. There was no concentric limitation of the visual field and no color-blindness. Buller attributes the sudden blindness in cinchonism to a rapid effusion into the lymph spaces around the nerve, producing an external strangulation, too transient to produce the phenomena of papillitis, but sufficient to produce cedema and blanching of the retina, and a permanent impediment to the blood-carrying capacity of the central arteries.

The dose of quinine sufficient to produce blindness is very indeterminate and largely depends upon idiosyncrasy. H. C. Wood has seen complete temporary blindness following the ingestion of 12 grs. Nearly always, however, the doses must be very large. Briquet thought that troubles of vision did not occur ordinarily until, for several days, doses of 1.5-2 grams (23-30 grs.), or for a single day doses of 3-4 grams (45-60 grs.), had been given. On the other hand, enormous doses sometimes fail to affect vision, though blindness always results when the dose has been lethal. Taussig<sup>46</sup> mentioned a dose of 1 oz. of sulphate of quinine given to a soldier suffering from ague. The only results were complete deafness and a kind of stupor, followed by recovery. Bryce<sup>47</sup> saw a child 2 years old, to whom 12 grs. of quinine were given daily for four or five days. Great prostration resulted, with unilateral paralysis, great oppression, pallid, cool and clammy skin, but no blindness. Barlow tells of a lady with severe congestive fever who took 40 grs. of sulphate of quinine every two hours for ten doses, or 400 grs. within twenty hours, without suffering from any injurious effects of the quinine, and who made a good recovery. Without doubt immense doses of quinine are frequently taken without disastrous consequences and, while blindness may be always expected in case of lethal poisoning, it is impossible to fix within definite limits the non-lethal doses that may be expected

to induce it. It unquestionably largely depends upon idiosyncrasy, and although it hardly ever develops except after the ingestion of large quantities of the drug, and even then with the greatest absolute rarity, the results are so terrible, that even the remote possibility of its occurrence should have influence in placing some check upon the lavishness with which quinine is but too often used in the treatment of disease.

#### QUININE DEAFNESS.

While *tinnitus aurium* and temporary diminution of the sense of hearing are the earliest and most characteristic symptoms of cinchonism, it is not a little remarkable that permanent alteration of the organs of hearing is very uncommon. So far as I have been able to ascertain, permanent complete deafness from quinine has never been recorded; indeed, complete temporary deafness is exceedingly rare. Briquet<sup>48</sup> saw but two cases. Giacomini and Gnersant<sup>49</sup> relate one case in which, after a single dose of 12 grams (180 grs.), there was complete deafness which only disappeared after several days, and another case, after taking 41 grams (615 grs.), in which hearing was restored very slowly. Records of incomplete temporary deafness from quinine are, of course, common enough, the symptom belongs to the ordinary pharmacology of quinine, but complete temporary deafness without concurrent amaurosis has but the scantiest authentic record. Joseph Williams<sup>50</sup> has noted such cases, in one of which hearing only began to return after three weeks and was never entirely restored. The patient was able to hear only those who addressed her in a very loud tone. Although there is a widely prevalent popular impression that quinine exerts a damaging influence upon the auditory apparatus, there is a singular dearth of definite proof that this action may be permanent. Most of those who prescribe quinine freely and in full doses are ready to declare that they have never witnessed such results, although every one admits that the drug most readily temporarily increases the difficulty of hearing of those who are already partially deaf. In a number of the cases of quinine amaurosis, however, the accompanying deafness never entirely disappeared, and popular opinion has received important confirmation in the declaration of a number of most competent authorities that quinine may be the cause of permanent aural defect; such writers, for example, as Roosa, Burnett, J. Orne Greene, Kirchner and others have so expressed themselves. Graefe, Hammond and Roosa early declared that hyperæmia of the auditory apparatus followed the ingestion of quinine. Roosa found that there was decided congestion of the blood-vessels which run along the *manubrium* in the *membrana tympani*. These vessels are intimately

<sup>46</sup> Med. Times, April 23, 1864.

<sup>47</sup> Medical Herald, Vol. iv, p. 441.

<sup>48</sup> Op. cit., p. 140.

<sup>49</sup> Dictionnaire de Méd., 2me edition. Art. Quinine, p. 567.

<sup>50</sup> Lancet, i, 1840, p. 639.

connected with those of the middle ear. The blood-vessels of the tympanum are also in direct communication with the circulation within the labyrinth. From the close connection between the vascular systems of the tympanum, the membrana tympani and the labyrinth, and from the appearance of congestion as the direct result of 10 and 15 gr. doses of quinine, we have evidence that the effect upon the ear is congestive rather than anæmic; but as the congestion visible is slight and disproportionate to the intensity of the tinnitus aurium, it seems reasonable to conclude that the congestion of the greater cavities is greater (J. Orne Greene).<sup>51</sup> In a most instructive article upon the same subject, Burnett<sup>52</sup> states that if to a healthy man from 15 to 120 grs. of quinine be given, a watch will only be heard at contact and bone conduction is abrogated. The membrana tympani assumes a hazy look, due to the intense congestion of the mucous surface of the drum membrane. The participation of the labyrinth is shown by inhibition of bone conduction and by inability to hear high notes by aerial conduction, or by a very limited power of perceiving them. This impaired power is due to the congestion in the lower whorl of the cochlea, where the nerve fibres for hearing for high tones are supposed to be. Important confirmation from experiment has been supplied by Kirchner.<sup>53</sup> Upon examining the labyrinth of a cat after large doses of quinine, Kirchner found hyperæmia and excessive extravasation of red and white blood cells extending from the *vas spirale* over parts of the *sulcus spiralis*, the auditory pillars, Corti's arches and the *membrana basilaris*. In three of ten rabbits he found, under similar conditions, extravasations extending from the semicircular canals to the vessels in the surrounding osseous substance in the temporal bone (Burnett). Greene, Roosa and Burnett are all convinced that great injury to the hearing is often produced by the drug, and in occasional cases the changes are no longer limited to simple hyperæmia, but otitis has been produced by it (Roosa,<sup>54</sup> Burnett).

Very singularly, the effects of quinine upon the sight and hearing appear to be attributable to two quite opposite conditions. Upon the ear the action is decidedly hyperæmic, upon the eye it is even more pronouncedly anæmic. How these changes are induced is quite unknown. It is generally assumed that they depend upon influences exerted through the vaso-motor centre. Regarding the ear, Kirchner concludes that the cause of the pathological changes after quinine is probably a vaso-motor disturbance whereby not only transitory alterations are excited, but also a paralysis of the vessels with congestion and exudation in the different parts of the organs of hearing. With

this condition of the aural blood-vessels and the narrow contraction of the retinal blood-vessels concurring, it seems difficult to refer the alterations to a central vaso-motor lesion. It is altogether more probable that the vaso-motor effects are local. It should be noted that the blindness is not necessarily associated with deafness. In some instances (few indeed), amaurosis has been present with little or no aural disturbance (Roosa, Voorhies).

#### GENERAL POISONING FROM CINCHONA PREPARATIONS.

Doses of cinchona alkaloids that are sufficient to produce complete deafness and blindness are often the cause of general symptoms of an alarming, even dangerous character. Bochefontaine,<sup>55</sup> arguing from results obtained in animals, concludes that in order to place the life of a man in jeopardy, 10 grams (150 grs.) of sulphate of quinine must be injected under the skin, or 16 grams (240 grs.) of sulphate of cinchonine administered in the same manner. He estimates the lethal dose by the stomach to be 35 grams (525 grs.) of quinine, or 50 grams (750 grs.) of cinchonine. These doses, however, exceed the amounts that have been known to produce death. I have already detailed a case of Baldwin's, where a negro girl died after convulsions produced by 20 grs. of sulphate of quinine given in forty-eight hours. This dose appears almost too small to be followed by such results, but the symptoms (described in 1847) tally so closely with those of more recent observations, that Baldwin's claim would seem to be well founded. Briquet reports two fatal cases, in one of which death followed the administration of 100 grs. in two days. The other patient (from Recamier) took nearly 120 grs. in doses of 5 grs. repeated every hour. Nevertheless it is pretty safe to assert that in order to produce death from quinine, enormous doses are necessary. Voorhies'<sup>56</sup> patient, it will be remembered, took an ounce within a few hours, and an equal amount was given each day for two days by stomach and rectum. She was in a critical condition for some hours, but recovered. The soldier who took one ounce at once with but unimportant consequences has also been referred to. It is certain, however, that doses that may prove dangerous are frequently prescribed and taken with reckless freedom. The practice has elicited protests from a number of writers. Dr. A. A. Smith<sup>57</sup> has written a vigorous paper upon this subject. J. Williston Wright relates several cases illustrative of the peril following excessive doses. One of his patients was a child 10 years old who took within twelve hours 25 grs. of sulphate of quinine by the mouth and 25 grs. by the rectum. Within two hours after

<sup>57</sup> New York Medical Journal, Vol. xxxix, 1884, p. 116.

the last dose, the child fell into a state of collapse, with a temperature of 93.9° F., a pulse of 60, very weak and intermittent, a respiration of 32, shallow and gasping. The face and lips were cyanosed, the skin cool and moist. Recovery followed. Even small doses may produce in some predisposed individuals symptoms that excite alarm; and no reference is made here to the distressing and violent seizures following even the smallest doses in some persons, in whom severe acute gastric catarrh, extensive cutaneous eruptions, active circulatory disturbances are observed. Lente,<sup>58</sup> for example, records a case where two small doses of calisaya elixir threw the patient, a woman, into a comatose condition. She had cold extremities, a hot head and symptoms of cerebral congestion. Lente relates other similar cases. A number of the cases detailed in the foregoing pages also presented alarming general symptoms.

In more severe cases the patients may pass into a condition bordering upon collapse. There will be extreme prostration, with or without loss of consciousness, or coma, lowered temperature, gradual weakening of the pulse and respiration, and chilling of the entire surface, copious cold sweating, deafness, dilatation and immobility of pupils, blindness, lividity or cyanosis of the countenance. Convulsions have occurred in a goodly number of reported cases. Both of Baldwin's cases had them; one, however, without losing consciousness. In this man, they began with a jerking of the whole body and great restlessness, anxiety and alarm. The convulsive movements came on every ten or twelve minutes, sometimes of the whole body, at other times of the arms. Briquet quotes Talbot as having seen convulsions follow very large doses. Pereira<sup>59</sup> records among cases of typhoid fever treated with 4 grams (60 grains) of sulphate of quinine daily, four who developed epileptiform fits. Gruening's patient, who took 80 grains in 36 hours, had convulsions shortly after the last dose. These were characterized by twitchings of the facial muscles and jerking of the upper and lower extremities. Although the patient denied all knowledge of the fits, Gruening thought that she did not lose consciousness during them. Similar extreme action has been noted by Ghose.<sup>60</sup> The patient was a Hindu female, 35 years old, who took, for remittent fever, 20 grains of quinine in four pills, one hourly. After the third pill she became insensible and convulsive movements of the limbs set in. After two hours she remained insensible, lying on her face with both hands clinched. Her eyeballs were turned upward and her pupils dilated. The muscles of mastication, of the arms, hands, and lower extremities in a condition of tonic con-

traction. The reflexes of the soles, palms, and even of the conjunctivæ, were abolished. The woman had never been hysterical.

Fatal cinchonism has very rarely been observed. Several such have already been referred to; within a few years two very interesting accounts have been published, the one, a case of poisoning by sulphate of cinchonidine (Winters), the other by sulphate of quinine (Lamb). Winters'<sup>61</sup> patient was a cachectic boy, 5 years old, who had remittent fever. By mistake he was given 32 grains of sulphate of cinchonidine every second hour until 128 grains had been taken within six hours. None was rejected. Winters saw him one hour after the last dose. He had then had three general convulsions of an irregular character. The temperature was 94.6° F., the pulse almost imperceptible at the wrist. By auscultation the cardiac pulsations were found to be 74. The skin and mucous surfaces appeared utterly bloodless. The pupils were dilated. The child was semi-conscious. The condition of sight and hearing was not noted. Despite stimulants, heat and friction, the boy gradually sank and died, apparently of exhaustion, eight hours after Winters first saw him after the poisoning. The necropsy revealed engorgement of the cerebral sinuses with dark, slightly coagulated blood. The brain was anæmic throughout. The left heart was contracted, but not firmly, and was empty. The right heart contained a small quantity of dark colored blood. Lamb's<sup>62</sup> patient was also a little boy. He was 3 years old. He had found a package of eighteen 3-grain sulphate of quinine pills and had swallowed them all. After a few hours he died, apparently of syncope. At the necropsy several of the pills were found undissolved, and Lamb estimated the amount actually absorbed to be 42 grains. Curiously, the cardiac conditions post-mortem were exactly unlike those found in Winters' case. The heart was relaxed; the right cavities were empty, the left cavities contained a little fluid blood. It was also discovered that the child had a mild but unsuspected typhoid fever.

In the cases in which convulsions occurred it is not clear that they were dependent upon the "nervous perturbation" that is so often seen in cinchonism. Comparative experiments upon animals show, however, pretty definitely that while quinine cannot be considered a convulsivant in the same sense in which strychnine is held, convulsive movements of an irregular character are pretty constantly provoked. As long ago as 1847 Baldwin found, after giving large doses to dogs, at first great restlessness, then vomiting, and occasionally purging. Next followed tremulous movements with a constant motion of the head, resembling that of paralysis

agitans. There was loss of consciousness, followed by complete paralysis of the hind extremities. In every case, where the doses were sufficient to produce death, except one, convulsions were observed. Bochefontaine's researches led him to the conclusion that both cinchonine and quinine are convulsivant, the latter less so than the former. This author, with Sée,<sup>63</sup> attributes a similar physiological action to cinchonidine, and quotes Chirone and Curci<sup>64</sup> as entertaining similar views. According to Soulier<sup>65</sup> the first effect of quinine is to produce an acceleration of the pulse, then, after a variable time, according to dose, to slow it. In warm blooded animals the first phenomena observed are lateral movements of the head, accompanied by general enfeeblement and incoördination of movements. The enfeeblement becomes pronounced, and vomiting occurs. The animal sinks down upon its thorax and neck and then, but only in a certain number of cases, epileptiform and even tetanic spasms occur. These, however, may be only secondary. Bruntton,<sup>66</sup> who has seen epileptic convulsions apparently caused by medicinal doses of quinine, acting through a stimulation of the motor centres, explains that in fatal poisoning the animal dies in convulsions consequent on stimulation of the nerve-centres by the venous condition of the blood produced by failure of the respiration. The loss of voluntary and then of reflex movement indicates that quinine acts upon the nerve-centres in gradually abolishing their function. In the fatal poisonings from quinine, the vagus nerve becomes paralyzed and death occurs through failure of respiration, and only occurs through cardiac paralysis if the drug be injected into the blood in large quantities. Douvreur's experiments with animals with sulphate of cinchonidine show that after lethal doses the heart slows and the blood-pressure progressively diminishes and reflex movements gradually grow feeble and are finally abolished, at the same time with the respiratory movements.

While it may be freely admitted that the dangers of lethal poisoning by quinine are very remote, it is certain that not sufficient attention has been given to some of the graver consequences that may follow its administration. In addition to the blindness and deafness which we have already considered, might probably be added abortion as a possible result of cinchonism. As, however, the oxytonic action of quinine has not as yet been determined satisfactorily, this aspect of the question will not be introduced at the present time.

DR. LYSTER, of Detroit, remarked regarding

the use of quinine in large doses, that he quite agreed with the doctor preceding him that only such portion of the dose as was required to neutralize the malarial intoxication was appropriated; any excess of dose was eliminated from the system usually without any markedly injurious effect. He believed that quinine was strongly antiseptic, and that the combination of alkalies and mercurials on account of the ptomaines and leucomaines existing where the quality of the bile was so inferior as it generally is in cases of malaria, then we have passive congestion of the liver and a lessened alkalinity of the bile. The conditions are quite similar to that observed in cirrhosis of the liver. The very large doses frequently repeated will not be required if such other valuable antiseptics be exhibited at the same time. The hypodermic use of the quinine should be made in suspected cases of the congestive or malignant variety in regions where such cases were met with.

DR. W. J. SCOTT said that the doses of quinine should be in size suitable to the necessity for its administration. He thought excessive dosing of quinine may do harm.

DR. DE SCHWEINITZ, of Philadelphia, had a case under his care in which amaurosis was caused by 12 grains, and lasted several hours. There is a case recorded by a French writer of a soldier who took over an ounce. Safety depends upon the precipitation in the intestine by alkaline juices of an acid salt.

#### SUSPENSION AND EXTENSION IN THE TREATMENT OF SCIATICA. A NEW USE FOR AN OLD INSTRUMENT.

*Read in the Section of Surgery and Anatomy at the Fortieth Annual Meeting of the American Medical Association held at Newport, R. I., June 25, 1889.*

BY CHARLES C. HUNT, M.D.,  
OF DIXON, ILL.

So unsatisfactory have been the results of the various methods of treatment of sciatica that any means whereby this painful disease may be cured, or even palliated, will be welcomed by professional men and laity alike. It has been my good fortune, in the past five years, to be able to give immediate and permanent relief in many cases of sciatica, especially of the chronic type, that had failed to obtain relief by any other means than those I am about to describe. The method is simple and, in my hands, has proved in the highest degree effective. I can better illustrate by the recitation of a few typical cases.

Mrs. K., a young married woman, no children, had pain along the line of the left sciatic nerve for over two years. It was so severe at times as to confine her to bed for several days, and at no time for many months had she been

<sup>63</sup> Comptes rendus des Séances de l'Académie des Sciences, No. 96, 1883, p. 1081.

<sup>64</sup> Rev. des Sciences Méd., Vol. xviii, p. 47.

<sup>65</sup> Thèse de Paris, 1883, p. 53.

<sup>66</sup> Pharmacology, Therapeutics and Materia Medica, 3d American Edition, p. 947.

able to perform her ordinary household duties without great suffering. I saw her as an office patient in May, 1884. Her general health was considerably out of repair, owing to chronic endocervicitis, right lateral retroversion of uterus, chronic sciatica of the left side, and consequent anæmia. I was inclined to the view that the uterine displacement and cervicitis, with their attendant anæmia, stood in direct causative relation to the sciatica, and I accordingly placed her on ferruginous tonics and resorted to such local measures as the nature of the uterine disorders indicated. After several months her general health was much improved; the uterine troubles had disappeared, but the sciatica continued with little or no material abatement. I then subjected her for another two months to the usual routine treatment for chronic sciatica, with no better success. Prior to my seeing her she had been for about eighteen months under the care of a very able physician, from whose treatment she had derived but little benefit. Early in November, 1884, I was visiting another patient at this lady's house. She informed me, on this occasion, that the pain in her hip was worse, that her increased cares had kept her much upon her feet, and she had now become almost helpless from the paroxysms of pain, which tortured her during the day and deprived her of her rest at night. Almost in despair I said to her: "If you will lie in bed two or three weeks and submit to such treatment as I think proper, I may succeed in curing you. I am not sure how matters will turn out. I have never tried this before, nor do I know of anyone else who has. In any event, it will do you no harm." She was glad to submit to any reasonable means that offered the least promise of relief. I had it in my mind to see what could be obtained by rest and extension, and as I had a Hodgen's splint at hand, it occurred to me that these, together with suspension, could be very readily gained by means of this most excellent apparatus. I accordingly adjusted this splint in the usual manner. In a few hours the pain had entirely ceased. She enjoyed the first good night's rest in over two years. At the end of a fortnight I removed the splint and permitted her to get up; but as a precautionary measure I left the adhesive straps remaining, so that at night, or in case of return of pain, she could attach a ten or twelve-pound weight to the limb by means of a cord passing over a pulley at foot of bed, in same manner as we ordinarily make extension in fractures of the lower extremities. This she kept on for three weeks longer, attaching the weight at night. The result was all that could be desired; the pain never returned after the first day. She was discharged cured at end of five weeks. I had the privilege of examining patient quite recently. She informed me she had been perfectly well of the sciatica ever since the splint was removed, nearly five years ago.

Henry C. M., a young unmarried man of very irregular habits. Had been a debauchee and lain out nights in a state of drunken stupefaction. Some two years prior to my seeing him, had contracted a severe form of sciatica. Upon examining him, stripped, I found marked atrophy of muscles of left thigh and leg, mobility of the limb much lessened, extreme tenderness on pressure over line of sciatic nerve, general health tolerably good. Had been under all sorts of treatment by all sorts of persons without deriving any material benefit therefrom. He was making a desperate effort to reform. His circumstances, he thought, would not admit of confinement in bed, and insisted that I try other means first, in hopes that he might obtain relief without being subjected to so severe an ordeal as the wearing of a splint necessarily implied. The interrupted faradic current, massage, nerve stretching, deep local injections of ether, etc., etc., together with such internal medication as suggested itself from time to time during a period of several weeks, were followed by only temporary alleviation. He finally consented to have splint applied, which was done March 11, 1886, at his home twelve miles distant. The first few hours gave great relief, but the dragging pain during the night became so intolerable that he telegraphed me next morning to visit him without delay. Arriving at his bedside, I found that too much tension was the cause of the difficulty, and as soon as this was lessened to a proper degree by the removal of the bed a few inches in the direction of its foot, the trouble ceased. He wore the apparatus two weeks, and kept up extension at night four weeks more, when he was discharged cured. I examined him about a year afterward, and found that the atrophy had almost entirely disappeared, his sciatica had not returned, and he had obtained perfect use of the limb. Some months after this he felt so jubilant over his restoration to health that he "took a drink with a friend." This was the initial step towards a grand spree, which lasted until his death, some weeks afterwards.

Mrs. S., a large, fleshy woman, 55 years old, always in good health except for the last year, during which she had suffered from sciatica, right side. October, 1885, applied the splint, which was removed after a fortnight. Extension by means of weight and pulley continued two weeks longer, at the end of which time patient was discharged cured.

W. C., blacksmith, sciatica left side, two and a half years' duration. Dipsomaniac. Acute attack, superimposed upon the chronic, caused by injury while shoeing a horse. Applied splint at once. Relief was immediate. Wore apparatus thirteen days, night extension two weeks. Discharged cured. I examined this case last week, that is, five months after removal of splint. He assured me he was entirely well.

Mr. S. Y. had been a severe sufferer from sciatica of right leg for over ten years. For last two years has been comparatively free from it, owing, as he thought, to three applications of a strong Faradic current. Was thrown from his wagon and sustained an injury of the right hip, inducing an acute attack of great severity. At first he would not consent to confinement on his back; insisted upon the use of electricity, as it had "cured him before." After gratifying his whim in this regard for several weeks, applied the Hodgen, February 1, 1889. By next day all pain in the hip had ceased. Wore apparatus fourteen days, night extension about ten days longer, when he removed the adhesive straps of his own accord. I am, at this writing, not fully informed as to the result in this case. He has called at my office several times since, but I happened to be absent each time. At the time I removed the splint, however, the progress was satisfactory.

EXPLANATION OF CUT.

K K, K K, the two arms of splint. E E, D D, sliding hooks on arms to which lateral cords E B E and D B D are attached. H H, cross-bar of splint, to which block covered by lateral straps is fastened by strap P. N, wire bail. A B, suspending rope passing over hook or pulley A, and returning is attached to itself by wooden "check" W. O and S, lower ends of arms. R, adhesive strap seen emerging from underneath roller at T and passing over block H H, is reflected upon leg on other side.

But to recite further would be only recapitulation. These cases are not selected ones. They are picked up at random from a list extending over a period of five years. No medicine of any

kind was administered to any of these cases during the treatment by suspension and extension, except an occasional laxative or cathartic. No opiates were required. In all, the relief was marked and decisive within from one to six hours after the proper adjustment of the apparatus. Recovery was completed in from two to six weeks, except, possibly, in the last one, the history of which I have just narrated as far as known.<sup>1</sup>

The etiology, pathology, diagnosis and general treatment of this morbid condition do not fall within the scope and purpose of this paper. Doubtless these departments will have been exhaustively considered in the paper to be presented to this Section by Dr. Carpenter, of Kentucky. My purpose has been solely to present a few clinical facts which are new and interesting, to me at least, at the same time cherishing the hope that they may prove no less so to those to whom I have the honor to relate them. I will only add, in this connection, that from the first I was surprised and gratified at the results obtained by this simple procedure. Rest, suspension and extension are, it seems to me, the three cardinal points in the treatment of this disease; and after an experience of five years I have nothing to add to, or substitute for, the Hodgen splint, as the most feasible means whereby these objects may be fully secured.

The apparatus was devised by the late Prof. John P. Hodgen, of St. Louis, during the War of the Rebellion. Its object was to maintain apposition of the fragments in gunshot fractures of the thigh while the wounds were being dressed. Its use in simple fractures has never been general. It consists of a one-fourth inch iron rod, bent in two places at right angles, so as to form two nearly parallel arms united by a transverse bar (see "H H" in figure), and of sufficient length to reach from the hip-joint to about four inches below the sole of the foot. These arms are slightly bent at the knee, and the upper ends are kept apart by a heavy wire bail (N). Five or six strips of heavy muslin roller, from three to five inches in width, are passed from arm to arm underneath the limb. These are fastened by means of safety pins along the outer arm of the splint, from the bail to near the ankle, so as to allow the limb to rest upon them, as in a cradle. Care should be taken to see that these strips press equally all along the under surface of the limb. Two strips of Maw's mole-skin plaster are adjusted to the leg, as is usual for extension by means of weight and pulley; these straps are separated below the foot by the usual block, which latter is now made fast to the cross bar of the splint by means of a strong piece of adhesive strap at the point "P." From the sliding hooks "E E" and

<sup>1</sup> Since preparing this paper S. Y. came in (June 20th) and reported himself entirely well.

"DD" are two heavy cords, which are united at "B" by a three-sixteenths inch rope, which passes up over a hook in the ceiling and back upon itself, where it is attached by means of the well-known device represented in the figure at "LM." The limb is raised or lowered by means of the wooden check "W." The suspending rope, "AB," should form, with a horizontal line, an angle of about sixty degrees. To prevent the patient from sliding down in bed, the foot of the bed should be elevated about four inches.

The late Prof. Frank H. Hamilton, in his justly celebrated work on "Fractures and Dislocations," declares, in regard to Hodgen's and all other suspending apparatus, that "whatever other excellences they may possess, this (extension) does not belong to them." How this distinguished author could have incorporated such a palpable error in a work so carefully written, I shall not attempt to explain. That this "suspending apparatus," when properly adjusted, *does* produce extension, even to a degree greater than one can bear, I have seen demonstrated over and over again. In a case of oblique fracture of the thigh of a very muscular man, with two and a half inches shortening, I sat by the bedside and witnessed extension, by this means alone, of sufficient power, without any anæsthetic, to bring the fragments into place. Indeed, there is danger of obtaining too much extension, as I have already related. This unpleasant circumstance may be obviated by instructing the patient, in case the tension becomes uncomfortable, to slide a few inches toward the foot of the bed, or have the bed drawn a few inches in the direction of its foot.

In cases of adults, especially of those beyond the average length, the bed should be seven feet long and without any foot-board; otherwise the lower end of the splint will press against the foot-board and extension will cease.

The apparatus can be made in an hour by any ordinary blacksmith. The wearing of it produces no discomfort. The calls of nature can be attended to with the least possible disturbance. Patient may even sit in a reclining chair, while his bed is being put in order, and it will do no harm if the suspending rope is unhooked for an hour or so at a time, while the bedding is being changed, the patient, in the meantime, sitting in a chair with limb (in splint) resting upon another chair. It is well, however, not to remove tension for this purpose until after one or two days.

While this method may not prove absolutely successful in all cases and under all possible conditions, yet it has, in my hands, been followed by such uniformly good results that I feel warranted in commending it to the favorable consideration of all, and especially of those who, like myself, have failed to obtain satisfactory results by other means.

## MEDICAL PROGRESS.

**SURGICAL TUBERCULOSIS.**—In a series of lectures recently delivered by MR. HOWARD MARSH at the Royal College of Surgeons of England, he gives the results of his own experience in the treatment of this disease:

As regards the general group of tubercular diseases met with in surgery, when they are detected early and are adequately treated by prolonged rest, in not more than 10 per cent. do they develop to any formidable degree. It is a rule with but few exceptions in the lecturer's experience that when, for example, a knee or an elbow, which is the seat of tubercular disease of less than three months' duration, is enclosed in well-fitted splints and is kept at rest, the case gives no further real trouble, and improvement, though slow, goes on until the joint is apparently free from disease, while after a longer period of rest complete recovery is secured. The period required for treatment in early cases does not, as a rule, exceed twelve or eighteen months. In more advanced cases the same treatment will lead to good repair. The treatment adapted for hip disease has been that of prolonged rest, with weight extension. In cases of suppuration all abscesses have been opened as soon as detected. An incision from an inch to an inch and a half in length is made, matter is evacuated by gentle pressure, and a small drainage tube, just long enough to enter the cavity, is used for two or three days and antiseptic dressings are applied. In many instances the wound closes in two or three weeks, sometimes sooner; in others it becomes a sinus which discharges for a month or six weeks and then heals; in others still, suppuration remains free for several weeks, or even longer, and further openings have to be made; but at length, in a large majority of cases, the wound heals and no further suppuration, except in a very few cases, takes place.

Mr. Marsh proceeds to give an analysis of seventy-six cases which had been operated upon in the Alexandria Hospital, the patients having been summoned for inspection a year and upwards after operation. Of these seventy-six patients thirty-seven were cases which had suppurated and thirty-nine cases which had not suppurated. Among the thirty-seven there were two cases of double disease, and in the thirty-nine there was one double case. Of the thirty-seven suppuration cases only four still had sinuses, and these were all small and superficial. The general results were as follows: One was a perfect recovery, six were excellent, seventeen were good, thirteen were moderate.

*Amount of shortening:* Three no shortening; 17 less than an inch; 12 between 1 and 2 inches; 3 more than 2 inches.

*Movement:* One perfect; 10 free; 7 slight; 18 fixed; 1 not observed.

*Walking:* Two perfect; 22 well; 13 indifferently.

Of the 39 non-suppurating cases 9 were perfect recoveries, 9 excellent, 12 good, 9 moderate.

*Shortening:* Eight none; 19 less than 1 inch; 11 more than 1 inch.

*Movement:* Nine perfect; 10 free; 10 slight; 10 fixed.

*Walking:* Twelve perfect; 20 well; 6 indifferently; 1 not noted.

The lecturer believes his figures of results obtained to be typical and in marked contrast to those obtained after the operation of excision, the mortality in the former amounting to about 10 per cent., while at a moderate estimate the mortality of the latter exceeded 20 per cent. With these satisfactory results in view he feels like advocating conservatism in treatment, and the more so because the main defect of excision, after all, will lie in the ultimate result, as regards the usefulness of the limb. Thus, in children the immediate result of excision of the knee may be all that could be desired, while the ultimate result is unsatisfactory in that deformity ensues and the functions of the limb are materially interfered with.—*Brit. Med. Journal*, Aug. 3, 1889.

**SECONDARY SYPHILIDES OF THE VAGINA.**—M. BALZER (Congrès Internat. de Der. et de Syphil., Paris) dwells upon the importance of careful inspection of the vagina for the discovery of syphilides. For this purpose the examination should be preceded by vaginal irrigation. The vaginal ampulla is their favorite seat. The papular form is the more common, and it may be isolated or associated with the papules of the cervix. The eroded form is also met with in the ampulla in the form of macules or simple striae with a reddish or whitish surface. Both forms usually heal quickly. When there are cervical plaques vaginal syphilides sometimes develop immediately upon contact, notably in cases of uterine anteversion. In the case of a prostitute who had had syphilis for more than four years there was a large mucous plaque of the vagina which developed in this manner, but which could only be seen after replacement of the uterus. The cervix was hypertrophied and ulcerated, but did not present a distinctively syphilitic appearance. It is reasonable to suppose that plaques may develop in syphilitic patients upon mere contact with a cervix that is the seat of a chronic ulceration. The papular or eroded syphilides are easily recognized and are scarcely to be confused with certain flattened vegetations or soft papular chancres of the vagina.

In the middle portion of the vagina syphilides are less frequent than in the ampulla. In one case there were ulcerations, apparently deep, which furrowed the vagina throughout the greater

part of its extent, but when the vaginal folds were carefully stretched out it was found that in reality the ulcerations were only superficial. In another case there was an ulcerous syphilide. The patient, who admitted having infected a person, was carefully examined a number of times with negative results. Finally, after an extremely careful examination, two ulcers were found midway in the vagina on the right side; they were concealed in folds of the mucous membrane, were circumscribed, with indurated borders, and bled readily. A mixed tonic treatment was ordered, but the ulcers healed very slowly. It is almost unnecessary to insist upon the gravity of vaginal syphilides in view of the contagious character of syphilis, but it is all the more important to search from time to time for manifestations of the disease in other parts of the body.—*La Semaine Méd.*, August 28, 1889.

**CASES OF ENTERO-VESICAL AND ENTERO-TUBAL FISTULÆ.**—F. P. KUTHE (*Weekblad v. h. Ned. tid. v. Geneeskunde*, 1889, No. 21), reports the case of a man 25 years old, who had long suffered from diarrhœa. All at once he noticed the escape of gas from the penis during micturition, at the same time faecal matter appeared in the urine. The communication was probably with the ileum, since opiates did not prevent the appearance in the bladder of the fluid contents of the intestine, although they produced constipation. Colotomy was, therefore, not available. Direct operative closure of the communication appeared to be the sole remedy. The patient being syphilitic, an antisyphilitic treatment was tried, and, contrary to all expectations, was crowned with success. The following year the same condition reappeared, but yielded to treatment of mercury and iodide of potassium, the patient remaining cured at the end of seven years.

In the case of entero-tubal fistula, the first indication was the discharge of gases, and an irritating fluid from the vagina. The diagnosis was confirmed by the introduction of vaginal tampons moistened with salts of lead, the reaction with sulphuretted hydrogen being conclusive. The daily introduction of iodoform bacilli led to a moderate improvement.—*Cent. für Klin. Med.*, 1889, No. 34.

**STENOSIS OF THE TRACHEA, FOLLOWING TRACHEOTOMY.**—(*Virchow's Archiv.*, B. cxvi, H. 1.) A child of 3½ years that had been subjected, two years previously, to tracheotomy, was obliged to continue the use of the canula on account of suffocative attacks. Finally attacks of dyspnoea appeared during expiration, even with the canula *in situ*, and during such an attack the child died. In such cases of tracheal stenosis as this the chief symptom is the appearance of suffocation whenever an attempt is made to withdraw

the canula. The reporter, having in a former report given an account of the various forms of tracheal stenosis upon a pathological-anatomical basis, desires to deal at present with those changes which are directly caused by tracheotomy and the canula. In spite of properly directed incisions and suitably fitting canulae, granulations form in the upper and lower angles of the wound and, later on, form an obstacle to the removal of the canula. Important changes in the tracheal cartilage and walls may be the result of too large or too small incisions, or deviations from the median line; or, aside from these causes, may be the result of unsuitable canulae. The reporter has studied these relations in preparations of the larynx and trachea taken from children upon which the operation has been performed, and has found that, to a greater or less extent, the cartilage becomes necrotic or assumes a false attitude. When the necrosed cartilage is removed, the defect heals by granulation and, later, by cicatricial tissue. Stenosis of the trachea is relatively more frequent outside of the hospitals, where the operation has often to be performed in the midst of trying surroundings. In these instances particularly he advises a careful control during the first few days of the anatomical relations as a prophylaxis against the production of stenosis.—*Cent. f. Klin. Med.*, 1889, No. 34.

**THE USE OF PESSARIES.**—DR. J. B. W. NOWLIN, of Nashville, Tenn. (*Southern Practitioner*), sums up his objections to the use of pessaries in the following terms:

1. They can only act as palliatives. If too small they are expelled or cannot sustain the womb, and if too large they exert injurious pressure.
2. They keep up a continual irritation in the vagina, acting as a foreign substance, producing mucous, purulent and leucorrhœal discharges, thus laying the foundation for fungus or cancerous diseases.
3. Many forms of these instruments are liable to produce septic results.
4. They produce undue and permanent dilatation of the vaginal walls by destroying the tonicity of the parts.
5. If not frequently removed, they become filthy and irritating.
6. They are liable to cause irritation of the bladder and constipation.
7. Their application is often left to the laity.
8. By the obstruction which they offer to the circulation, they produce engorgement, and it may be ulceration of the surrounding parts, extending even to the production of a vesico-vaginal or rectal fistula.

**GONORRHOËAL ARTHRITIS.**—DR. A. MYRTLE, of Harrogate, Eng., reports two cases of this

character. In both there were the ordinary symptoms of rheumatic arthritis of very severe degree, and in addition to this a remarkable wasting of the muscles of the thighs and legs, which was both sudden and persistent, confirming the views of some authorities that certain centers of the cord and brain are partially paralyzed by the reflex sympathy existing between them and the inflamed urethra; the wasting of the muscles in the limb not affected with the special joint mischief is decidedly in favor of that opinion. In the two cases reported, the treatment was eminently satisfactory and was as follows: Cotton, wool and flannel applied to the joints; two 12-ounce tumblers of old sulphur water an hour before breakfast as an aperient, and an 8-ounce glass of the mild sulphur water at mid-day. Later passive motion and slight massage. Hot sulphur douche at the baths followed by rubbing with camphorated oil.—*Brit. Med. Journal*, Aug. 3, 1889.

**OVARIOTOMY IN RUPTURE OF A MULTICULAR CYST.**—M. POLAILLON reports (*La Semaine Méd.*) the case of a woman in whom a diagnosis of ovarian cyst had been made and who, while raising herself in bed after taking a purgative, experienced a crackling sensation in the abdomen accompanied by severe pain. During the three following days symptoms of peritonitis appeared, with typhoid, vomiting and severe pain. On the third day laparotomy was performed and a multilocular cyst weighing 3 kilogr. removed. At the upper portion of the tumor one of the pockets, which contained a blackish-looking fluid, was found ruptured. There were well-marked appearances of peritonitis. Fibrinous membranes were removed and the toilette of the peritoneum made with a warm antiseptic solution. The patient rallied well from the operation and bids fair to make a good recovery. M. Polaillon remarks that in rupture of cysts the effusion, if serous, may be reabsorbed; if gelatinous it is not reabsorbed and the patient is exposed to the dangers of peritonitis; in rupture of a myxosarcomatous cyst he has seen a veritable graft of pathological tissue upon the peritoneum.

**ANTIPYRIN.**—Antipyrin bids fair to become an universal panacea. DR. W. F. WRIGHT, of New York, says that he has employed it in migraine, trigeminal neuralgia, ovarian neuralgia, muscular rheumatism, hysteria, and certain spasmodic conditions, in all of which he has found it of distinctive value. He has also obtained excellent effects from its employment in the insomnia of exhausting and irritating diseases, especially in combination with chloral. By French authors it has been described as possessing valuable hæmostatic properties; thus, Hénocque considers that the drug produces a con-

striction of the vessels and the tissues, while coagulating the blood. In epistaxis he uses it in powder, solution, gauze and ointment. Hinkel (*N. Y. Med. Journal*, Oct. 30, 1888) has used a 4 per cent. solution with good effect in cases of hæmorrhage following operations on the nose. He also finds that it exerts a sedative action in cases of sneezing, coryza, etc., while combined with cocaine it increases the topical action of the latter, enabling it to be used with effect in weaker solutions. Carl Lowe (*Ther. Monatshefte*, 1889, 169) has used antipyrin in many cases of whooping-cough occurring in an epidemic, and found it a very valuable agent except in a few cases, in two of which the symptoms seemed to be aggravated by its administration, and in one of which the toxic effects of the drug were manifested.

The *Berliner Klin. Wochenschrift* (No. 17, 1889) reports marked success following its introduction in the treatment of whooping-cough, but also takes occasion to point out the dangers of poisoning from its administration, a cumulative action having been observed in some cases.

**SUPRAPUBIC CYSTOTOMY.**—MR. H. T. HERRING reports thirty-one cases of this character performed by Sir Henry Thompson, who at the end of 1888 had completed a series of more than 1,000 cases in which he had operated upon the bladder for calculus and for tumors. Of the thirty-one cases of suprapubic cystotomy two were performed by the old method and the remainder by the modification suggested by Garson and first introduced into England by Thompson. The chief points of this modified method were to commence with a fully yet prudently distended rectum, followed by a fair distension of the bladder; a sparing use of the knife; the opening of the bladder by a small incision sufficient to admit the finger, but enabling further enlargement to be made by dilatation only, since after this the opening contracts and stitching is not necessary, and moreover appears to be generally not advisable.

In the first series (two cases by old method) both patients died. In the second series there were eleven cases of tumor of the bladder and eighteen cases of calculus. Of the eleven cases of tumor only one was fatal, and that from pyæmia. Among the eighteen calculus cases there were three deaths, exclusive of one in which death was due to an attack of bronchitis and asthma. The whole of these cases represent the most advanced and the most complicated examples of disease, and were on that account not amenable to lithotrity, or to a perineal section of any kind.

**TYPHLITIS CAUSED BY A DATE STONE.**—DR. E. G. ARCHER reports a case of a farmer, aged 35, who, when first seen on June 26th, was suffer-

ing from symptoms of intestinal obstruction. For some time he had experienced constant uneasiness in the bowels, for which he had taken aperients, resulting the day before in copious evacuations. The treatment consisted in opiates and hot applications, followed by castor oil. On June 28th a large accumulation of feces was passed, giving great relief to all the symptoms. In this discharge a date stone was found. Improvement was only transitory and an abscess formed, bursting into the bowel on July 5th, after which the patient made a rapid recovery. The patient had not eaten dates since the preceding Christmas, and accordingly the date stone must have been in the bowels for at least six months.—*Brit. Med. Journal*, Aug. 3, 1889.

**SPONTANEOUS VERSION.**—DR. T. W. EVANS, of Richmondale, Ohio, reports a case with the following notable particulars: The patient was first seen June 16th, at 2 A.M. Up to this time she had felt no pains, although there had been copious discharges of liquor amnii on the previous day. Upon examination a hand was found protruding from the vagina in a dorso-posterior position. The arm was easily replaced, after which the head came down. Two hours later the patient was again visited. At this time she was having strong expulsive pains, and an examination revealed a breech presentation. Labor terminated favorably.—*Medical and Surgical Reporter*.

**SNAKE BITES.**—DR. L. G. LINCEUM, of Lampasas, Tex., reports (*Southern Practitioner*, Sept., 1889) that he has treated more than one hundred cases of bites inflicted by poisonous reptiles, and that he has never seen a case result fatally that was treated by the hypodermic administration of permanganate of potassium and the administration of chloroform locally and by means of inhalation. He gives the permanganate in one and two grain doses.

**FLOATING KIDNEY.**—DR. J. T. B. BERRY reports a case of floating kidney in a woman otherwise healthy. Six weeks after the discovery the patient was attacked by peritonitis, to which she suddenly succumbed. Dr. B. presumes that the peritonitis was set up by the escape of some fluid into the peritoneum, possibly from an abscess of the kidney, or from rupture of the ureter.—*N. O. Med. and Surg. Journal*.

**SALVE FOR INFANTILE ECZEMA.**—DELAPERT gives the following in the *Revue de Thér. Méd.-chirurg.* of Sept. 1:

R. Boric acid . . . . . 5 jss.  
Vaseline . . . . . 5 j.  
Balsam of Peru . . . . . grs. viij. m.

Sig.—Apply the ointment frequently to all the affected parts.—*Medical News*, Sept. 21, 1889.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 68 WABASH AVE.,  
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, SEPTEMBER 28, 1889.

PROFESSIONAL ORGANIZATION.

Recently we have been favored with several announcements of new Tri-State and District Medical Societies, every one of which may be regarded as a finger-board, pointing to a restless, working element that permeates the entire medical profession. The omen is for good and indicates a craving desire for a more thorough professional organization than now exists.

The first of these district organizations to arrive at distinction is the Mississippi Valley Medical Association, that has recently held its fifteenth annual session at Evansville, Ind. The type and character of the papers and discussions of that meeting compare favorably with those of any similar organizations of which we have knowledge, while we have reason to believe that the work to be done by the other and more recently organized societies will be valuable, a credit to their distinct organization and to our guild.

One of the notable outcroppings of the meeting at Evansville was the expressed desire on the part of nearly all of the members, that the American Medical Association would officially recognize the Mississippi Valley Medical Association, and all similarly organized district and tri-State societies, as actual branches of that body. The importance of such a movement can scarcely be overestimated, as it practically proposes a feasible plan for a unification of the entire medical profession of this country.

It is easily understood that, on account of the long distances that separate the great medical centres where the annual meetings of the Amer-

ican Medical Association are held, there is a constant fluctuation and practical change of active membership. Moreover, the American Medical Association being in its organization a body composed of delegates from affiliated State, county, and other local societies, the same persons are not every year sent as delegates, all of which conduces to a constant disintegrating process, that is actively detrimental to the strength and efficiency of this parent organization of American physicians.

Through the organization of district and tri-State societies that are geographically limited in area, which invite the presence and active coöperation of every member of the regular medical profession within their bounds, it would be possible to obtain not only a professed, but an actual allegiance of more than forty thousand active members. Even this number is only about one-half of those who claim to practice regular medicine.

In this more complete organization a certificate of membership issued by any branch, should receive and have the same recognition as if it were issued by the parent organization.

One of the grand purposes of this thorough organization of branch associations, would be the ability to practically institute a system of collective investigations of disease, and of any department of the sciences, which would in their results be of inestimable value. In fact, the treasury would warrant the inauguration of a system of original scientific research that would not only be a stimulant to every thinking worker in our domain, but a source of pride to every American physician. It would be impossible to comprehend the amount of good that may be accomplished in this direction.

The members of the American Medical Association, some six years ago, believed it to be in the interest of the entire profession that it should have a journal that would not only be the official organ of the Association, but that it would in time become the principal avenue of intercommunication in the entire medical profession, and thus become a practical bond of union. It now assumes its functions in a direct effort to guide the profession in a way that looks to a thorough harmony and complete unification of the entire body of American physicians. The spontaneous growth, and enthusiastic support of the geographical district

medical associations indicates a plan by which a methodical unification may be accomplished. It is desirable that this official channel of intercommunication in the profession shall be placed in the hands of every physician. This may be brought about through the annual payment of dues in the branch associations, in precisely the same manner as adopted in the American Medical Association, so that every member would in this manner obtain the Association journal. A by-law providing that any member who has once paid his annual dues of five dollars should on exhibition of a certificate to that effect be exempt from a second payment, and only required to pay a small sum to defray the current expenses of the additional meeting, or meetings which he may attend.

In this manner the Association journal would not only be the official organ of the American Medical Association, but would also bear a similar relation to all the branch associations, and thus may it be made a veritable mirror, to reflect the very best thoughts of the very best minds in the entire realm of medicine. We need, we must have a practical and harmonious unification of the entire medical profession of this country.

#### TREATMENT OF POTT'S PARALYSIS BY EXTENSION.

In the *American Journal of the Medical Sciences*, May, 1889, DR. S. WEIR MITCHELL relates how, becoming dissatisfied with the progress of cases of paralysis from spinal caries under the customary treatment, he had recourse to the device of partial suspension by the head, which he believes to have been first systematically practiced by his father, Prof. J. K. Mitchell, with satisfaction to himself and benefit to his patients. The extension is made by a sling suspended from a curved iron made movable and set by a screw, which can be attached to a chair, thus allowing the patient to sit up and, if necessary, to be taken out of doors in that position. The amount of extension used is gauged by a spring balance, and, beginning with a slight pull and regulating the amount of force used by the patient's sensations, may be increased, in some cases, to as much as seventy pounds, and used from four to six hours in the day. By this means he has been able to rectify curvatures and to restore motion, sensi-

bility and nutrition in cases which had been unsuccessfully treated by rest in bed, the plaster jacket and the usual topical and constitutional treatment. He concludes as follows :

"My conclusions are that suspension should be used early in Pott's disease.

"That, used with care, it enables us slowly to lessen the curve.

"That in these cases there must be, in some form, a replacement of the crumbled tissues.

"That unless there is a great loss of power, the use of the spine car or chair, etc., of John K. Mitchell enables suspension, especially in children, to be combined with some exercise.

"That no case of Pott's paralysis ought to be considered desperate without its trial.

"That suspension has succeeded after failures of other accepted methods.

"That the pull probably acts more or less directly on the cord itself, and that the gain is not explicable merely by obvious effects on the angular bony curve.

"That the now well-known influence of extension in Pott's palsy makes it probable that in other forms of spinal disease not due to caries, extension in various forms may be of use, as has apparently of late been made clear.

"That the methods of extension to be used in these and in various cases may be very various, only provided we get active extension.

"That the plan and the length of time of extension must be made to conform to the needs, endurance and sensation of the individual case."

#### EDITORIAL NOTES.

##### HOME.

THE OHIO STATE DENTAL SOCIETY will hold its fifth annual meeting at Cleveland, on October 30, 1889.

CANADIAN MEDICAL ASSOCIATION.—*The Canadian Practitioner*, in an editorial on the recent Annual Meeting of the Canadian Medical Association in referring to the representatives from the United States, says :

"Our brethren across the imaginary line are ever welcome at the meetings of our societies. The United States certainly sent a very able contingent to Banff. Never has the Canadian Medical Association had more distinguished visitors. Among them were Drs. Curry and Whittaker, of

Cincinnati; Drs. Gibney and Bulkley, of New York; Dr. Barker, of Philadelphia; Dr. Marcy, of Boston; Dr. Hannan, of Albany, and others. They took an active interest in the proceedings of the meeting and engaged freely in the discussions when called on. We were glad to meet them, sorry to part from them, and we hope they will visit us again next year in Toronto. In the meantime we have been asked to visit them. Let us do so."

DOMINION MEDICAL ASSOCIATION.—Officers elected for following year:

President, Dr. James Ross, Toronto.

Vice-Presidents, for Ontario, Dr. Bruce Smith, Seaforth; for Quebec, Dr. Lachapelle, Montreal; for Nova Scotia, Dr. Johnston, Sydney Mines; for New Brunswick, Dr. Holden, St. Johns; for Prince Edward Island, Dr. McLeod, Charlottetown; for Manitoba, Dr. Spencer, Brandon; for Northwest Territories, Dr. Brett, Banff; for British Columbia, Dr. Edwards, Nanaimo.

General Secretary, Dr. James Bell, Montreal.

Treasurer, Dr. W. H. B. Aikens, Toronto.

Local Secretaries, for Ontario, Dr. Farley, Belleville; for Quebec, Dr. Elder, Huntingdon; for Nova Scotia, Dr. Muir, Truro; for New Brunswick, Dr. Raymond, Sussex; for Prince Edward Island, Dr. Warburton, Charlottetown; for Northwest Territories, Dr. Higginson, Winnipeg; for British Columbia, Dr. Rutledge, Moosomin.

THE AMERICAN RHINOLOGICAL ASSOCIATION meets at the Palmer House, Chicago, on October 9, 10 and 11, 1889.

THE SANITARY CONDITION OF LOS ANGELES.—We regret to learn that a proposition to issue bonds for the construction of a sewer to the sea has been defeated by a popular vote of the citizens. The necessity for the successful carrying out of some plan to relieve this fair city from the noisome and sickening odors arising from the so-called sewers now in existence, may be judged from a paragraph which recently appeared in a local paper:

"Los Angeles is a city of from 70,000 to 80,000 people. It is almost without sewers. More than three-fourths of it has no sewerage at all. The small sewers we have are choked and overflowing, and foul matter is often forced out of them. Sewer gas from leaks and overflowing sewers

floats in the business centers at night, and in the residence portions the air is heavy with foul odors and gases from neighboring cess-pools. The soil of the city is in general such that it does not absorb the foul matter, and that renders the situation worse. In many parts of the city the odor at nights from cess-pools is so strong that residents are obliged to close their windows. Children are dying with diphtheria as a result of these cess-pools."

To longer delay action will be worse than criminal. Money should not count where the health of the people is at stake. We trust that the press of California will so arouse public opinion that this blot on the escutcheon of the gem of the Pacific coast may be removed, and Los Angeles once more regain its reputation as a health resort.

THE AMERICAN RAILWAY SURGEONS will hold their next annual meeting at Kansas City, Mo., in May, 1890.

TYPHOID FEVER is epidemic at Negaunee, Mich. Over 100 cases are reported.

#### FOREIGN.

THE CONTINENTAL ANGLO-AMERICAN MEDICAL SOCIETY.—The first general meeting of this society will take place at the Grand Hotel, Paris, on Monday at 5 P.M., and the first annual dinner will also take place at the Grand Hotel at 8 P.M. on the same evening. The following gentlemen are Honorary Presidents of the Society: Sir Spencer Wells, Sir Joseph Lister, Dr. Richard Quain, Prof. Ball, Prof. Brown-Séquard, Dr. Ricord, Dr. J. S. Billings, Dr. Fordyce Barker, and Dr. Weir Mitchell. The Executive Committee includes the Hon. Alan Herbert, M.D., Dr. Faure Miller, Dr. Chapman, Dr. Dupuy, Dr. Barnard, with Dr. T. Linn (16 Rue de la Paix) as Secretary.

CHILD MORTALITY IN DUBLIN.—An extremely interesting and suggestive paper, by Dr. Grimshaw, Registrar-General for Ireland, entitled "Child Mortality in Dublin," may be found in the July number of the *Dublin Journal of Medical Science*. The paper deals largely with the relations subsisting between child mortality on the one hand and drunkenness and crime on the other, and is based upon a careful tabulation of the vast amount of statistics at the command of the author. Among other matters of interest, Dr.

Grimshaw establishes the fact that the mortality of children in Ireland as a whole, is lower than in England and Scotland, because the relative proportion of the urban population in those countries far exceeds that of Ireland, while the death-rate of town children far exceeds that of country children; that notwithstanding the foregoing, the child mortality of Dublin is comparatively high, both in relation to that of the cities of England and Scotland and that of the other large Irish cities; and that the extremely intemperate habits of the lower classes in Dublin have much to do with this high death-rate. The children of drunken parents, says Dr. Grimshaw, are not born healthy, and when born are neglected in every conceivable way and are exposed to dangers from reckless negligence which are almost inconceivable. A comparison between the rates of mortality and the rates of drunkenness, as measured by the criminal statistics of large towns, shows that there is a close relationship between the two, the carelessness with respect to child life being shown by the large proportion of children who die without being medically attended during their last illness.

NEW PAMPHLETS ON HYPNOTISM.—The recent appearance of two pamphlets in the German language on the subject of hypnotism is an indication that the interest taken in this subject is by no means confined to the French physicians. The first of these, by E. Baierlacher, Stuttgart, is entitled "The Therapy of Suggestion, With its Technique." The second, by F. Müller, treats of "Hypnotism and Suggestion, as Well as Their Therapeutical Application."

MR. CLARK BELL, of the Medico-Legal Society of New York, was recently tendered a reception by the President and Council of the Society for the Study of Inebriety, of London. A resolution was also adopted congratulating Mr. Bell on his services to legal medicine; on the effect of the discussions at the Medico-Legal Society of New York on criminal procedure in cases in which persons sentenced to death have been ultimately respited on the plea of insanity; on his efforts to abolish physical restraint in the treatment of insanity in the United States; and on his pleas for a reconsideration of criminal procedure in the case of inebriate criminals, who were often really irresponsible and subjects of a true disease calling for medical and not penal treatment. Mr. Bell,

in reply, spoke of the excellent state of English asylums for the insane, and dwelt strongly on the urgent need for a more humane and intelligent interpretation of the law as to inebriate responsibility.—*Brit. Med. Journal.*

COLOR BLINDNESS AND DEFECTIVE VISION.—At the last annual meeting of the British Medical Association MR. BICKERTON, of Liverpool, directed the attention of the ophthalmological section to the prevalence of color blindness in the merchant marine, and the insufficiency of the tests now employed for its detection. He proved by the inexorable logic of facts that not only has this particular variety of impaired vision been productive of serious mischief, but that defective "far sight" in officers and look-outs must clearly be held responsible for numerous disasters at sea. The time seems to be now ripe for parliamentary action, and Dr. Farquharson will ask the President of the Board of Trade whether it is the case that a departmental committee has been appointed to consider the whole subject, and whether their report will be presented to the House before the end of the present session.—*Brit. Med. Journal.*

REPORTS OF EPIDEMICS.—The French Minister of the Interior, with a view to receiving regular reports upon the sanitary condition of all parts of the country, and to be able to arrest, as promptly as possible, the spread of epidemics, has requested the Minister of Public Instruction to call a meeting of the principals of schools, in order to establish a new plan of statistics. This will consist in a bulletin setting forth the appearance of epidemic diseases in the schools, which shall immediately be forwarded to the sub-prefect under cover of the Mayor of the commune. A quarterly report of the epidemic affections which have made their appearance during the preceding three months is also to be made. These statistics will be revised in the offices of the sub-prefects and transmitted, through the various departments, to the Minister of the Interior under stamp of the department of "*Assistance et de l'hygiène publiques.*"—*Le Bulletin Médical.*

A STATUE has been erected in Courtrai, Belgium, to Palfyn, the celebrated anatomist of the eighteenth century and Professor of the University of Gand.

## TOPICS OF THE WEEK.

## THE MEDICAL STUDENT OF THE FUTURE.

An editorial in the *British Medical Journal* of Sept 7th makes special reference to the student of the future. From it we make the following abstract :

We may assume without the least offense that most men enter on the study of medicine as the means of obtaining an honorable living ; it is not necessary to pretend to any higher motives, like that which should influence a student of divinity. Yet there is room, we maintain, for the influence of the very highest motives in the choice of the healing art as one's calling in life ; and the influence is likely to have an actually greater scope, and the end is often even more likely to be achieved, when it is concealed by the friendly covering of the less exalted motive.

There are hundreds of medical men in our land to-day who lead lives of the loftiest enthusiasm, working for the good of their fellow-men, and blessing all within the scope of their influence, pretending with a beautiful humility that they are only following their common business, while they are actually ministering angels. A doctor may live and work for fees and be respected just as any other servant of the commonwealth ; he may also live and work for humanity and the love of his neighbor as though he were ordained for the proper work of the ministry. Grand and beautiful as was the work of Father Damien amongst the lepers of Molokai, there is no reason why a medical man should not have done as much, or even more. " Nothing great," says Emerson, " was ever achieved without enthusiasm," and we know it to be so, whatever the hard, cold world may say, which, in truth, does not greatly care for anything which it cannot quite understand.

What is wanted is a noble ideal ; given this, it may be exercised as freely in our profession as anywhere in this world of ours. What a man seeks at his medical school this October, that shall he find. Honors, they await him ; emoluments, they shall come ; happiness, the great enduring pleasure that comes from a sense of duty bravely done, this too shall be his, at the price—at a fixed price and no abatement ; to this let him make up his mind as quickly as may be. Let him examine himself and know what it is he wants ; he can certainly obtain it. Let the lower motive content him ; he will not be disappointed. Medicine is rich enough to pay him for his pains ; he shall have his house, his servants, and his gig ; shall be justice of the peace, mayor of his town, and be held in honor of men. A man, by indomitable energy and perseverance, may get all he wants. As Hazlitt somewhere says, he could always gain admittance to see any famous picture in any great man's home, notwithstanding the darkest frowns of the servants ; and he adds that he could, by similar means, have obtained any post under Government which he might have set his whole mind upon.

The thing, therefore, to be sure of at the outset in devoting one's self to medicine is the end proposed ; if self, then not happiness of the highest sort also ; if peace of

mind and the purest sort of happiness be the end in view, then to live and work for others, for the advancement of the profession in its widest and grandest aspects, is the only certain way to obtain them. Old Thomas Vicary, chief surgeon to St. Bartholomew's Hospital, 1548-62, says in his curious *Anatomic of the Bodie of Man*, that the doctor must be learned, must know his principles, be seen in natural philosophy, in grammar, must speak congruity in logic, speak seemly and eloquently, know things natural and non-natural, and, above all, be good-looking, for whose face is not seemly, it is impossible for him to have good manners.

All this implies much more than is demanded for the mere cramming up for professional examinations. Be liberal in your treatment of the most liberal of all professions, and give at least as much as you take. How few men ever think of paying the least fraction of their indebtedness to science ! They consider this all arranged for in their hospital ticket. Such men

Know, not for knowing's sake ;

Know, for the gain it gets, the praise it brings,

The wonder it inspires, the love it breeds,

No man striving only for his own happiness can ever attain it, because he is in the midst of forces contending against him, set in motion by every other man of the same determination. Count Tolstoi has admirably explained why this struggle for individual happiness must necessarily fail of its purpose ; and Mr. Browning, in his magnificent poem of " Paracelsus"—which should be known by heart by every medical student of the thoughtful sort—has pointed out how mere knowledge for a selfish end can never bring happiness, whatever else it may achieve ; but that love, allied to knowledge, can transform the soul to God-like beauty. We may long, like Paracelsus in the poem,

To wring from Heaven some wondrous good for man ;

but it may not be given to many of us to do great things. Of every medical man, however, Society—having in view his great endowments, his privileges, his public estimation, and the dignity of his calling—has the right to expect maintenance of the fabric, if not its adornment ; and, as he is necessarily looked up to as a " doctor," that he shall be a real teacher how to live the highest mental as well as the healthiest bodily life. As Sir J. Crichton Browne pointed out recently, this can best be done by imbuing our own minds with the prolific and ennobling thoughts of the wisest writers of the past and present ; for to teach we must learn. Some will say we ask too much of the overtaxed medical student. Not so. The mental enlargement we demand can be had as relaxation between the intervals of necessary studies. One hour a day with the great poets and prose writers will enable the student to do better work in the medical school ; he will not lose his time by this form of dissipation ; and when he goes into the great world which lies outside his hospital he may find his own medicine and that of his patients in the balm for troubled spirits which the philosophers and poets of all time stand by to minister. We say he will not lose his time by this expansion of his education ; it will serve to digest his technical knowledge, to combine and blend his studies into a truer

and sounder learning than can be tested by examination papers or rewarded by degrees.

Let no student, therefore, think that so much anatomy, physiology, medicine and surgery, signed up and certified for at school and college, suffices to make the medical man of to-day. In one of the most suggestive of the inaugural addresses delivered in London last October, that by Dr. William Ewart at St. George's Hospital, this point was strongly emphasized. We cannot refrain from recalling a sentence or two. "Among the youths," says Dr. Ewart, "who elect to follow this calling, many do so in ignorance of what the choice implies. Of no other profession is it more true that an easy entrance examination is unkind. Ours, nowadays more than ever, is an exacting profession. Although neither genius, nor brilliancy, nor even talent are wanted, she claims energy, physical and mental, capacity for sustained efforts, earnestness, and a high moral tone."

A medical practitioner whose whole life is not that of a persevering student has no business in the profession. A man who knows nothing but what his curriculum enforces, and who makes haste to forget that as soon as it has obtained him his license to practice, can only bring discredit on the high-minded and cultivated men who spent their lives in making smooth the path he has unworthily trodden. If medicine is to hold its high position and retain the respect in which it is justly held, the men who are coming forward for its emoluments and distinctions must be equipped with all the richer learning which is required to enable them to hold their own in a world which is daily becoming more highly cultured, and which will certainly demand more of its medical advisers. A mental outlook bounded by six-ounce bottles and an intellect from which there is gradually fading the scanty lore gathered at the medical school with much pain and but partial comprehension far too generally characterise the middle-aged general practitioner of to-day. He of to-morrow will need to know more, and to know it in quite another way.

#### CREOLIN IN OBSTETRICS AND GYNECOLOGY.

DR. THEOPHILUS PARVIN has been employing creolin very extensively of late. He finds it valuable in cervical catarrh, in which he applies it at intervals of three days. In the strength of one teaspoonful to a pint of water it is used wherever a vaginal injection is indicated. Benzoated lard with the addition of 4 per cent. of creolin makes a reliable antiseptic ointment, useful alike to the obstetrician and gynecologist. Parvin makes use of this in tamponing the vagina in cases of descent or posterior displacement of the uterus. For this purpose a long strip of absorbent cotton smeared with the ointment is tucked alternately into the anterior and posterior cul de sac until the vagina is packed either partially or completely as the case requires. Such a tampon has been left *in situ* by Dr. Parvin as long as six days, at the end of which time the only odor detected was that of creolin. In obstetrical practice creolin possesses the advantage of revealing itself both by sight and smell, thus obviating

the dangers which accompany the use of sublimate and carbolic acid, which are often used in too strong solutions. Mixed with water in the proportion of one teaspoonful to the pint, creolin makes a milk-colored fluid. —*Practice.*

#### THE USE OF ANTISEPTICS BY COUNTRY SURGEONS.

The surgeon of the city, with all his expensive appliances and machinery and skilled assistance, may find the aseptic method of treating wounds practicable; but the country practitioner who must forego those aids, and who finds his patient oftentimes in anything but aseptic surroundings, must resort to other and simpler methods.

All my surgical instruments and dressings are carried in one small hand-bag. I have carbolic acid, tablets of corrosive sublimate and iodoform. Needles, knife-blades and other small instruments are kept in a 1-60 carbolic-glycerin solution. After using and cleansing, they are put back into this solution, and thus are always ready for immediate use. Other large instruments are put into a 1-40 carbolic solution some time before needing them. My bag contains silk on a reel, and drainage-tubing, both in a 1-4,000 solution of corrosive sublimate. Sterilized sponges are carried in a 1-1,000 corrosive sublimate solution, and suitable pieces of oiled silk are put in the same, some time before using.

After the flesh adjacent to the wound has been thoroughly washed, both skin and raw surface are bathed in a corrosive sublimate solution, the strength varying between 1-1,000 and 1-5,000, in inverse proportion to the extent of the raw surface. After the incisions are completed, the cut surfaces are washed for a considerable length of time in a 1-4,000 corrosive sublimate solution, hot enough to check bleeding, to blanch tissue, and to render the parts thoroughly aseptic.

For ligature I use silk, and cut the ends short. If the wound is a large one and necessitates the use of a drainage tube, I do not think that it makes much difference whether or no the ligatures are cut short. But if the wound be small, if there be no drainage tube, or if it be early removed, I consider that the long ends of the ligatures prevent absolute healing in a short space of time. These short silk ligatures either become absorbed or encapsuled. They give me no trouble, and I get healing by first intention through the full extent of the wound, which is not closed until every particle of oozing blood has ceased. For healing, I depend largely on the most careful and accurate approximation of the parts.

After the wound is closed, and thoroughly washed with a 1-4,000 corrosive solution, iodoform is used freely, as wounds seem to heal more kindly with it than without it. After this a piece of sterilized oiled silk large enough to cover the wound is applied. This is used for two purposes: to prevent the sticking of the dressings, and to keep the plasters which cannot be rendered aseptic from contact with the wound. Over this are placed several layers of sublimate or carbolic gauze, then a large piece of oiled silk to cover the whole, which is bandaged in the ordinary way. Subsequent dressings I do, if possible, myself, and make them as few and far between as

may be. On redressing, the wound is generally found to be so clean that the usual washing is simply a process of dampening with an antiseptic solution.

Since I began the constant and systematic use of antiseptics, I have seen most cases heal without a drop of pus. In simple amputation I have come to expect healing by first intention except around the drainage tube, and solid healing by from twenty-one to twenty-eight days after operation. As a rule, I greatly prefer the action of corrosive sublimate to that of carbolic acid as an antiseptic. But if I know of the existence of albuminuria, or suspect any latent tendency to disease or congestion of the kidneys, I am very careful to avoid it.

It will be seen that my method is exceedingly simple, so simple that it would hardly be a matter of interest except for the fact that its very simplicity makes it practicable, and this especially adapts it to the unassisted country surgeon. It is now something over two years since I have seen a touch of surgical fever in my own practice, and in uncomplicated surgical cases I have rarely seen a temperature above 100°. I now get healing of large cut surfaces by first intention, as a rule; formerly it was the exception.—DR. ROBT. BURNS, in *Boston Med. and Surg. Jour.—Weekly Medical Review*.

## SOCIETY PROCEEDINGS.

### New York Academy of Medicine.—Section on Orthopaedic Surgery.

*Stated Meeting, April 19, 1889.*

A. B. JUDSON, M.D., IN THE CHAIR.

#### PSOAS ABSCESS FOLLOWING POTT'S DISEASE.

DR. V. P. GIBNEY presented a patient, a girl 14 years years old, on whom he had operated for double psoas abscess following Pott's disease of nine years' duration. The carious vertebræ were evidently consolidated when last November large abscesses were discovered, and the patient was brought under treatment. On the right side the tumor was incised in Scarpa's space, and long forceps were passed under Poupart's ligament through the iliac fossa, and into the lumbar region, and a counter opening was made on the forceps along the border of the erector spinæ muscle. Pieces of bone escaped with the pus. The cavity was curetted and the bone scraped gently. With antiseptic dressing and injections of carbolic acid solution 1-40, and 1 per cent creolin solution, both wounds closed in a month. The left side was then operated on by simple incision and drainage. Large quantities of bone detritus were scooped out with the finger. A sinus still remains on the left side, from which a piece of bone is occasionally discharged.

The case was exhibited as showing the advantage of Owen's method over attacking simply the sac and not the whole suppurating track.

DR. GIBNEY believed it would have been better to have treated both sides according to Owen's method; but in general he doubted the propriety of doing this operation during exfoliation, which would necessitate a subsequent operation. It is also important that the patient should be in pretty good condition.

DR. R. H. SAYRE had used injections of peroxide of hydrogen in large abscess cavities with better results than from carbolic, or bichloride, or boro-salicylic solutions.

DR. GIBNEY said a similar experience had been reported by Dr. Vance.

DR. JUDSON thought that an objection to operating on these cases was that for the natural incarceration of the pus and detritus, we submitted an artificial opening, necessitating antiseptics to hasten cicatrization. If these accumulations are doing no harm, it is better to leave them for removal by natural processes; and if in due time they perforate the skin, the general and local conditions are ready to promote evacuation and speedy cicatrization.

DR. J. A. WYETH said that operation is indicated when large abscesses are situated on exposed parts of the body, and liable to injury and subsequent septic complications. He recalled the case of a woman who, thirteen years after being considered cured of Pott's disease, slipped and fell, striking a large gluteal abscess. The accident speedily gave rise to symptoms of sepsis with high febrile movements, and several operations under ether were necessary for the removal of bone detritus which was spread through the gluteal muscles. The patient ran great risks, but finally recovered. He had had other similar cases. A psoas abscess behind the peritoneum causing no trouble, should be left alone, but one pointing in the thigh, back, or other exposed situation, should be operated upon, as the danger of the operation is almost nil.

DR. N. M. SHAFFER was reminded of the history of a patient with Pott's disease and an abscess occupying the gluteal region and the anterior part of the thigh. The child fell, striking the gluteal tumor. The immediate symptoms were alarming, but without the adoption of any special treatment, the accident resulted in the entire disappearance of the abscess. If there were any means of determining with certainty when an abscess from Pott's disease contains bony detritus, it would be preferable to operate; but while spondylitis is still active, it is better to postpone operating as long as possible. He recalled a case of Pott's disease and hip joint disease which he had been watching for several years, where spiculae of bone as large as the end of the finger were expelled in a sudden and violent attack of coughing. The bone was undoubtedly from the cancellous structure of the sixth or seventh cervical vertebra. The patient

was relieved at once, and physical examination showed that very little trouble had been caused by the entrance of the bone through the lung tissue into the bronchial tubes.

**KNOCK-KNEE ; CLUB-FOOT ; DEFORMITY FOLLOWING HIP DISEASE.**

In a paper on "Osteotomy," DR. WYETH related two cases in which he had corrected in- and out-knee in the same patient by double osteotomies. The patients were 3½ and 4 years old respectively. Both were discharged entirely relieved. Strict antisepsis was followed and the limbs were dressed in plaster of Paris in a position of over-correction. He prefers MacCormac's incision on the outer side and just above the capsule, since the saphena vein and anastomatica magna artery are not endangered as in McEwen's operation on the inner aspect of the thigh. He also briefly related three cases in which patients, aged 13, 18 and 26 years respectively, had been relieved of the deformity following hip disease, and restored to good locomotion by operations on the femur. The method pursued was Gant's osteotomy below the lesser trochanter. The after treatment had been Buck's extension and Hamilton's long splint. In one of the patients there had been double hip disease. Two months after the left femur had been operated on, the right was operated on ; and four months after the date of the first operation the patient was discharged cured, with good locomotion.

He also related two cases in which congenital talipes equino-varus of the most exaggerated type had been corrected with good recovery, and with the feet in excellent shape. Tenotomy of the tendo Achillis, tibialis anticus, and tibialis posticus was first done ; the first two subcutaneously, and the last by open incision, the tendon being dissociated from that of the flexor digitorum, and divided on an aneurism needle. The operation was completed by an osteotomy as follows : An incision was made on the outer side of the dorsum, exactly over the point of greatest convexity ; the tissues were lifted from the tarsus by an elevator, and a conical section including portions of the calcaneus, astragalus, cuboid, and scaphoid was removed. The rule should be to remove all parts which prevent replacement of the foot. The foot being brought into normal position by eversion and rotation, aseptic dressing and plaster of Paris completed the treatment, the result of which was excellent.

DR. GIBNEY said that the anatomical point raised in the paper concerning supra-condyloid osteotomies certainly commends to us the operation of MacCormac. Although in- and out-knee in the same subject is rare, he had seen many instances of multiple deformity among Bohemians and Italians. He had recently done a sextuple osteotomy at one sitting, and is treating an un-

united fracture of the right tibia, all the others having united.

DR. JUDSON thought that in congenital talipes the reduction of the deformity by mechanical or operative means is easy ; but that is a small part of the necessary treatment. So long as the patient is growing he must be under occasional observation, and if necessary made to wear for a few months, at intervals of two or three years, a brace fitted to the present needs, in order to prevent threatened relapses. In the deformities of the knee there is especial reason for preferring mechanical means of correction, because here we have the advantage of the leverage found in the tibia and femur, while in club-foot there is only the tibia on one side, and on the other the short and many-jointed foot.

DR. H. L. TAYLOR said that late observation of the results of treatment is of especial importance in orthopædic practice. If surgeons and orthopædists would report the condition of patients five, ten, or more years after dismissal, a more intelligent choice of methods could be made.

DR. SHAFFER said that his experience with mechanical appliance in the treatment of talipes leads him to think that many severe operations are performed on patients who could be better treated by traction. He recalled a case in which there was confirmed equino-varus, although three or four tenotomies and five or six osteotomies had been performed. He had applied the "external lateral stretcher" and the patient is now walking on the flat of the foot. He referred to the interesting question whether osteotomy is advisable when there is motion in the hip-joint. In a patient, on whom Dr. W. T. Bull had operated, some motion was found after etherization. The reduction of the deformity by osteotomy had been followed by persistent traction with the hip-splint ; and good position and slight motion had both been retained.

DR. GIBNEY believed that the presence of motion is not a contra-indication to the operation. About six months ago he had performed Gant's operation for a right-angled deformity. The flexion had been reduced from 90° to 15°, and the limb was retained at 15° of flexion by a traction apparatus for three or four months, when it was removed and the patient allowed to walk about with a high shoe. After about six weeks the flexion had increased to 25° or 30°. Traction was re-applied, and the limb is being again brought down. He recognized the necessity of protective apparatus in order to retain or increase the result secured by operation.

DR. WYETH had operated in several cases where there was motion and had refused to do it in others. In a patient whom he had seen with Dr. L. A. Sayre, there was considerable motion, and he had done a tenotomy for temporary relief, postponing osteotomy.

DR. R. H. SAYRE said that in the case referred to, improvement had followed the tenotomy, but an apparatus is necessary to prevent a return of deformity. He thought that in some cases sufficient reduction of the flexion might be brought about by section of the psoas and iliacus muscles. This had been done in one case in which, although the operation had been subcutaneous, injury of the vessels had been avoided. By open section this danger would be avoided.

DR. J. D. WILSON expressed surprise at the frequent mention of elevations of temperature in the history of Dr. Wyeth's cases, which had been treated antiseptically. Have our teachings been too absolute, or do such temperatures really indicate imperfect antiseptics?

DR. WYETH replied that the "temperature of reaction," occasionally as high as  $102^{\circ}$ , occurred in the first twenty-four hours, but it usually fell to normal in forty-eight hours. Traumatism, ether, shock, and the use of sublimate combine to produce this reaction, which might still be called an aseptic temperature. He closes the discussion by saying that the simplicity and safety of osteotomy had been shown by the cases he had reported. While no case of equino-varus treated the first two years of life should require tarsotomy, neglected cases will present themselves where nothing but tarsotomy will give relief. The operation may give considerable foreshortening to the foot, but one can certainly correct the deformity, however great, by removing enough bone; and if this be properly done, he believed it to be real conservatism.

#### Association of American Physicians.

*Fourth Annual Meeting, held in the Army Medical Museum and Library, Washington, D. C., September 18, 19 and 20, 1889.*

#### WEDNESDAY—MORNING SESSION.

The Association was called to order at 10 A.M. by the PRESIDENT, DR. FRANCIS MINOT, of Boston.

The first business was the reading of the President's Address:

#### THE PROGRESS OF MEDICINE DURING THE LAST FIFTY YEARS.

The immediate causes of the great advancement of medicine were the growth of physiology and pathology, including bacteriology, and the improvements in clinical and laboratory teaching of the present day, which have led to a better acquaintance with the nature and causes of disease, to a more rational and successful therapeutics, and to the prevention by means of hygiene of a large number of diseases, including some of the

most fatal. These means have been greatly aided by the progress of science in general and by the conveniences of modern civilization, which enable observers from different countries to assemble together for interchange of knowledge and experience. A large share of medical progress is also due to the dissemination of knowledge by means of well conducted journals which enable thousands of practitioners who cannot leave their homes to be constantly supplied with the most recent discoveries relating to pathology and the diagnosis and treatment of disease. The organization of this Association is peculiarly adapted for the progress of medical science, representing no one section of our country, but including practitioners from all parts of the United States and Canada, whose experience, knowledge, observation and ability are brought together for comparison and for mutual instruction.

The President reported the death of the following members: Drs. H. D. Schmidt, New Orleans; John C. Dalton, New York (honorary member); Robert Palmer Howard, Montreal; and Edward T. Bruen, Philadelphia.

DR. C. F. FOLSOM, of Boston, read a paper entitled

#### THE EARLY STAGE OF GENERAL PARALYSIS.

The author first reported a number of cases illustrating the early stage of the disease in which the motor disturbances were very slight and might readily be overlooked and escaped detection. The striking loss of muscular control or power, generally considered a part of the disease, were not found until a late period of the disease. The mental symptoms consist in impairment of a peculiar quality, often so slight as to be made out with difficulty.

The disease arises most commonly under prolonged strain, particularly when associated with unaccustomed excesses. At least two-thirds of the general paralytics have had syphilis. The relation of the disease with syphilis is too frequent to be accidental. The disease is, however, not a stage of syphilis, and is not benefited by specific treatment. The prognosis is probably not so hopeless as it is generally considered to be.

The common early treatment is harmful. Foreign travel is injurious. The only hope of at least partial cure or marked amelioration is in entire mental and physical rest.

DR. ROBERT T. EDES, of Washington, reported the case of a man suffering from pronounced general paralysis, in whom the first symptoms of the disease made their appearance some twenty years ago. If the anatomical view of general paralysis is accepted he did not consider it strange that mental symptoms might precede the motor, depending upon the seat of the lesions.

DR. S. WEIR MITCHELL, of Philadelphia, was sure that certain cases of general paralysis began

most markedly with motor trouble, while others began most decisively with mental conditions. In regard to syphilis he agreed with the author, except that he had seen cases due to syphilitic disease in which cure had followed specific treatment. He had also seen cure follow in a small number of cases where the treatment was begun in the early stages, but where the motor disturbances and the mental incapacity were sufficiently marked to render the diagnosis reasonably certain. In all of these cases there had been a total abandonment of all previous pursuits with absolute mental and physical rest. He agreed with the author that foreign travel was often injurious.

DR. JAMES J. PUTNAM, of Boston, remarked that the fact that syphilis acts in this disease not by producing a direct lesion, but in an indirect manner, justifies us in looking for other causes of degeneration which might act in a similar manner. He asked if the reader had seen any cases in which chronic lead poisoning was the apparent cause of the general paralysis, and related a case in which the imperfect and slow speech, the imperfect handwriting and the expression of apathy and indifference suggested a diagnosis of general paralysis. In this case there was, however, a history of drinking of water contaminated with lead, and there were certain local symptoms indicating lead poisoning.

DR. WM. PEPPER, of Philadelphia, believed that he saw these cases from a different standpoint than that of Dr. Folsom. They came to him as cases of dyspepsia, lithæmic disturbance and the like, and are under his care for some time before symptoms leading to recognition are developed, sometimes for years before the parietic symptoms appear. He could not regard syphilis as in any way essential in the causation of general paralysis.

In regard to the early stage of the disease, there was not one symptom mentioned by Dr. Folsom or described by others as indicating the early stage, which he did not often find in cases of nervous lithæmia. There may be a grouping of these symptoms or a discovery on the part of the diagnostician which will enable a finer and finer shade of these differences to be recognized, which does constitute a basis of diagnosis. He thought that general paralysis could be initiated by many disturbing, depressing or irritating causes, and that in its early stages and slight degrees it was capable not rarely of being entirely cured. If these cases are permitted to go on with neglect of hygienic habits and with excesses, sexual, alcoholic or business, a notable proportion will end with symptoms of general paralysis.

DR. C. F. FOLSOM, of Boston, said in regard to lead that while he had seen cases in which this agent had produced symptoms similar to the initial symptoms of general paralysis, he had not seen a case in which the terminal symptoms of general paralysis had been produced. As illus-

trating apparent cures after specific treatment he referred to a case in which the use of large doses of iodide of potassium apparently produced complete recovery, and the patient returned to his previous business. The symptoms after several months reappeared and had continued to steadily progress. Whether this is the result in all such cases, he was unable to say.

DR. JAMES STEWART read a paper on

#### TETANY.

The details of the following case were referred to:

The patient, a male, aged 40, has been troubled during the past eight years with regularly recurring attacks of tetany. He served as a soldier during the American civil war. Suffered at that time and subsequently from chronic dysentery and malarial attacks. For upwards of ten years he has been troubled with diarrhœa. Patient is tall, emaciated and anæmic. The first subjective symptom of his tetany is usually double vision, which is quickly followed by the characteristic contractions of the flexor muscles of the hands. Occasionally the flexors of the fore-arms and the abductors of the arms become spastic, muscles of the face almost constantly suffer, muscles of the lower extremities rarely.

The affected muscles are the seat, during the attack, of fibrillary twitching. The attacks often last several days (seven to twelve), unless terminated by the very free use of morphia.

The galvanic irritability of the nerves is found to be greatly increased, also the mechanical irritability of both nerve and muscle. Knee-jerks exaggerated during attack, absent in intervals. Œdema of the hands and arms, with herpetic eruptions frequently to be seen after particularly severe attacks. The quantity of urine excreted during attacks is usually normal in amount, and contains urea and indican in great excess. Patient has been under observation for more than three years, and it has been noticed during the past two years that he has been getting gradually dull and apathetic. It takes him a long time to answer questions, he complains of general numbness, his face and lips are swollen, symptoms closely resembling those seen in myxœdema.

Tetany may be divided into three varieties:

1. Epidemic or "rheumatic" tetany, common in Europe, but extremely rare in America. The course is acute and favorable.

2. Tetany from exhausting causes, as lactation, diarrhœa, etc. Course is chronic and favorable.

3. Tetany from removal of the thyroid glands. Course generally is usually either quickly fatal or chronic and incurable.

4. A form of tetany occurring in cases of dilatation of the stomach. Very fatal.

Infantile tetany is excluded from above di-

vision, as what is so frequently called tetany in infants is not that disease. No doubt true tetany may occur in childhood.

DR. JOHN T. CARPENTER, of Pottsville, Pa., read a paper on

#### TETANY AND A NEW THEORY OF ITS PATHOLOGY.

The author defined tetany as a nervous disorder accompanied by tetanic spasm of an intermittent character, which may extend from the extremities to the jaw and be reproduced during the periods of intermission at will by pressing sure on the trunk of the affected nerve trunk or over the blood vessel obstructing the circulation.

A historical version of the disease was given. Tetany was regarded not as a special disease, but as a sequel of precedent phenomena only. The affection was regarded as the result of septic absorption. The diminution of cases of tetany coincident with the successful treatment and the prevention of septic poisoning, was regarded as an argument in favor of the connection between septicæmia and tetany. Cases illustrating this view were cited. The views previously held in regard to the pathology of tetany were discussed and considered as tenable.

DR. FRANCIS P. KINNICUTT, of New York: I have seen but two cases of intermittent tetany, both occurring in patients with dilatation of the stomach. In one the dilatation was due to pyloric stricture resulting from cancer; in the other there was non-malignant stricture. In both of these cases the conditions were favorable to absorption of poisonous matter.

DR. F. T. MILES, of Baltimore, reported the case of a young woman, aged 22 years. She had suffered from six to eight years from dilatation of the stomach. She had vomited acid matter, but never offensive. She had several times had numbness of fingers and toes. She suffered her first attack of tetany twenty-four hours before her death. In this case the stomach had never been washed out.

DR. A. JACOBI, of New York, had been struck with the stress laid by the readers upon sepsis as the cause of tetany. In one of the cases reported by Dr. Stuart which he thought was due to absorption of putrid material, the stomach was twisted, and Dr. J. suggested that the intermittent contracture was due to nervous influence, resulting from the twisting rather than to absorption. He did not doubt that there were cases in which septic absorption produced such symptoms, but when we recall the fact that the contracture is temporary, we must conclude that the influences giving rise to that attack were also temporary. Many of these cases are, I think, the result of nervous irritation. In some of the cases reported I should attribute the condition to anæmia.

DR. JAMES J. PUTNAM, of Boston, remarked

that the reported cases of tetany showed such a variety of infectious sources, that it seemed hardly probable that they should act in such a similar manner unless there was something else behind. Two or three things are to be considered: First, the influence of habit. The disease set up by a variety of causes may continue as a result of habit. Second, the suggestion that in such cases of disordered action we have to deal with an over-sensitiveness of physiological arrangement is important. In these conditions we have the disordered manifestation of what is really a function, but one not ordinarily recognized as it has no independent existence. It would seem that in the absence of further knowledge with regard to infection, and the manner this infection arising from various sources may act, we should insist upon the possibilities of explanation which are presented to us by what we know of the physiology and disordered physiology of the nervous system, in attempting to explain conditions met with in this and similar diseases.

DR. JAMES STUART, of Montreal, said in connection with the influence of peripheral irritation, that in the cases of dilatation of the stomach where tetany had caused death, the symptoms came on five hours after the stomach had been washed out. This would point to irritation rather than decomposition as the active cause in this class of cases. There are many other cases where infection could not enter.

DR. JOHN T. CARPENTER, of Pottsville, said in regard to anæmia as the cause of tetany, that we should have to go back of the anæmia to the cause that produced it. He knew of no cause that would produce anæmia so surely as septic absorption.

#### AFTERNOON SESSION.

DR. A. B. BALL, of New York, read a paper on

#### THROMBOSIS OF CEREBRAL SINUSES AND VEINS.

The author first referred to the influence of the following factors in the production of thrombosis: 1. Blood stasis; 2. Vessel lesions; and 3. Blood changes. The anatomical conditions in the sinuses that favor thrombosis were described at length. A number of cases of marantic thrombosis of cerebral veins and sinuses in chlorotic girls.

The symptoms were next considered. Much importance has been attached to distension of external veins collateral to the internal veins supposed to be affected, giving rise to hæmorrhages and œdema. These signs are frequently absent and may be due to other conditions. The mobility of the symptoms has been considered of value. In these cases the cerebral symptoms undergo strange alterations not seen usually in other affections. Active delirium is exceptional.

The depression continues but alternates with a certain amount of improvement. Fever is absent at first, and if present is to be attributed to complicating conditions. Paralytic symptoms of varying extent are usually present. With the exception of the variation in degree the paralysis does not differ from paralysis from other causes.

DR. WILLAM OSLER, of Baltimore, exhibited two specimens illustrating the conditions described by Dr. Ball. The first specimen was one of extensive thrombosis of the lateral sinus occurring in a man who died from phlegmonous erysipelas of the cheek. There were no special symptoms in that case.

The second specimen was from a woman dying of consumption. It was thought that gradually increasing coma and the onset of cerebral symptoms were supposed to be due to basilar meningitis.

DR. A. JACOBI, of New York, enumerated certain additional aiding causes. The first was a disproportion between the white and red blood corpuscles. The second cause was the relative absence of muscular tissue in a number of the veins. A third cause was absence of water in the blood, often due to the withholding of sufficient fluid in the diet of patients. The last cause referred to was weakness of the heart. When in exhaustive diseases the heart is allowed to become feeble, thrombosis, with all its bad results, must be expected. It is certainly a good therapeutic measure to stimulate and strengthen the heart in every disease that will last long or tends to terminate in exhaustion.

DR. WM. H. WELCH, of Baltimore, said: There is one point of great force in explaining the production of thrombosis; that is the possibility that there is some form of intoxication analogous to that produced experimentally by various substances, such as the fibrin ferment. Under such circumstances there is almost instantaneously extensive thrombosis wherever the ferment reaches. Pathologists are aware of the frequency with which thrombi, usually of a mixed character, are found in the cerebral sinuses, particularly the superior longitudinal sinus, in cases that have presented no symptom during life.

DR. SAMUEL C. BUSEY, of Washington, D. C., read a paper on

#### THE EFFUSION OF CHYLE AND OF CHYLE-LIKE, MILKY, FATTY FLUIDS INTO SEROUS CAVITIES.

The object of the paper was to present the subject of effusion of chyle, chyle-like and fatty fluids into serous cavities. It was limited to the effusion of such fluids into the cavities of the pleuro-peritoneum and tunica vaginalis.

*Effusion into the pleural cavities, Chylo Thorax.* Of this, including the doubtful cases, there have been ten cases reported. In five of these the

chyle poured directly from the thoracic duct. The diagnosis in these cases can only be made by evacuation and examination of the fluid. The prominent symptoms are dyspnoea and accumulation of fluid in one or both cavities. The prognosis is unfavorable and the treatment expectant.

*Effusion into the tunica vaginalis testis.*—The case of galactocoele reported by Vidal (de Caasis) seems to have been the first observation of this class of effusions. In two of the reported cases the paludous orifices of the vessels from which the lymph exuded were found. Since 1885 there have been reported in this country thirteen cases in which filaria were found, and two of these were cases of lymphocoele. It has not been shown, however, that filaria are present in every case of lymphocoele. The recent invasion of portions of the sub-tropical belt of this country by the filaria, and the reports of cases of disease with which the parasite has been so uniformly associated, together with the fact that the mosquito has been proven to be its intermediate host, present consideration of the highest importance to the profession and general public.

*Chylous and oily ascites.*—A tabulated statement arranged chronologically, presenting a condensed summary of the reports of cases of chylous and oily ascites, was given. The number of cases reported was thirty-three. Primary rupture occurred in but five cases.

The symptomatology of effusion of chyle into the peritoneal cavity is not sufficiently distinctive to differentiate such cases from ordinary ascites, and a diagnosis is only possible after examination of the evacuated fluid. Of the 33 cases 19 died, 9 recovered, and in 5 the result is not stated. Of the 22 cases of chylous ascites proper 12 died, 5 recovered, and in 5 the result is not stated. Meagre and unsatisfactory as are the clinical details of these cases, they point to two conclusions: 1. That a free and unobstructed channel of communication between the venous system and the chyle conveying vessels is essential to the proper nutrition of the body and preservation of life. 2. That death following the partial or complete obliteration of this communication is the result of inanition.

DR. WM. OSLER, of Baltimore, said that in ordinary post-mortem works it was not infrequent to meet with varices of the chyle vessels of the mesentery covering the walls of the intestine. Sometimes there are extravasations which may form large chylous cysts.

With reference to chyluria he was positive that there was a non-parasitic form. He had made thorough examinations in one such case and failed to find filaria. On post-mortem examination nothing was discovered. Also in a case of lymph scrotum, he had examined the fluid and the blood and had found no embryos. He laid a great deal of stress upon these cases, as it is gen-

erally stated that these conditions are always parasitic.

DR. W. H. WELCH, of Baltimore, exhibited a specimen of chyle removed from the abdominal cavity of a boy 12 years of age. He described the chemical and microscopical characters of the fluid, and dwelt upon the importance of distinguishing between chylous and fatty hydrops.

DR. J. F. A. ADAMS, of Pittsfield, Mass., read a paper on

#### SUBSTITUTES FOR OPIUM IN CHRONIC DISEASES.

The disadvantages attending the use of opium are: 1. In an overdose it is a poison. 2. In ordinary doses its benefits are largely offset by various functional derangements. 3. Its use involves the danger of the opium habit.

Remedies that may be substituted for opium for the relief of pain. The antipyretics, antipyrin, acetanilide, phenacetin and exalgin have well grounded claims to be regarded as rivals of opium. They are, however, less certain and less prompt, particularly when pain is very violent. Antipyrin in five to ten grain doses had been found valuable as an analgesic particularly in headache, neuralgia and rheumatism.

Acetanilide he had found less active than antipyrin. He used it in doses of seven or eight grains. He had found it particularly serviceable in lumbago and dysmenorrhœa. In the latter condition one or two doses has afforded prompt relief.

Salicylic acid and its sodium salt should be included on account of their marked effect in the relief of pain in rheumatism, particularly its acute form.

*Substitutes for opium to induce sleep.*—Paraldehyde is an excellent hypnotic, although rather uncertain. Hydrate of amyl is generally preferable to paraldehyde, being more reliable as well as more agreeable. Sulphonal is more extensively employed than either of the above, and is applicable to all forms of insomnia.

*Chronic diarrhœa.*—It is probable that no remedy has been used in this affection so largely as opium. The effects of this mode of treatment have been far from satisfactory. Recently the author had treated these cases antiseptically with far better results. The remedy chiefly used has been sodium salicylate in five to ten grain doses three or four times a day. He had also used salol with success.

DR. G. M. GARLAND, of Boston, referred to the value of the fluid extract of gelsemium as a substitute for opium. In frontal headaches it has an admirable effect. It is used also with advantage in difficult and painful menstruation and certain forms of neuralgia. As a simple hypnotic gelsemium answers well in cases of temporary congestion with insomnia and headache. In hysterical conditions this agent will often induce

sleep in a short time. The drug is given in doses of five to ten drops every half hour until the desired effect is obtained or its physiological effect is produced in diplopia and ptosis. These appear sufficiently early to serve as a warning.

(To be concluded.)

## DOMESTIC CORRESPONDENCE.

### LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

*Meeting of the Fifth District Branch of the New York State Medical Association—The Excursion to Milford, Pa.—Mr. Rudolph Hering's Report on the Sewage System of New York—The Suicide of Dr. Tilden Brown—The Power of an Artificial Electric Current to Destroy Life.*

The seventh special meeting of the Fifth District Branch of the New York State Medical Association was held at Port Jervis, Orange County, the last week in August. The place of meeting was the parlors of the Fowler House, and the session was one of interest both from a scientific and social point of view. The first paper was by Dr. W. B. Eager, of Middletown, on "The Use of Concentrated Lactic Acid." He had employed this agent with success in the case of epithelioma and other conditions, and, in fact, wherever acetic and nitric acids are generally used as escharotics.

Dr. J. H. Hunt read a paper on "The Treatment of Typhoid Fever," with special reference to the cold water method. It was accompanied by carefully prepared charts, with details of temperature, pulse, etc., and elicited a prolonged discussion, in which many valuable points were brought out. Dr. Alfred L. Carroll, of New York, exhibited a small and inexpensive apparatus, devised by himself, for the rapid estimation of CO<sub>2</sub> in atmospheric air. He said that the apparatus generally used was more or less expensive because the jar was accurately divided off into cubic centimetres, and on account of the accompanying mechanical contrivances. This one was made out of an ordinary pickle jar, a couple of rubber or cork stoppers, two or three feet of small rubber tubing, and three or four pieces of best glass tubing. Dr. H. B. Swartout, of Port Jervis, then read the notes of a case of empyema. The patient was presented for examination by those present, and the case was discussed at some length. An elaborate paper by Dr. T. H. Manley, of New York, who was unable to be present, on "Injuries of the Skull, with some Observations on One Hundred and Fourteen Cases," was read by title, on account of the lateness of the hour, and the Branch then adjourned, after a very interesting session.

Almost forty Fellows attended the meeting, and

a considerable number of them remained over night to go on a most attractive excursion to Milford, Pa., and the Sawkill Falls beyond, which had been provided by the Committee of Arrangements, of which Dr. J. H. Hunt, of Orange Co., was chairman. The company occupied two large eight-seated wagons, and thoroughly enjoyed the magnificent drive, over a road that might compare in smoothness with those in Central Park, through one of the most romantic regions in the country. Milford has always been noted for its exquisite scenery, which has long made it a favorite resort for artists, and on account of the numerous rains during the past summer, the rich foliage and the many beautiful mountain streams were at their very best. The weather was delightful, making every one feel in the most jovial spirits, and after their exhilarating drive to the north Sawkill Falls, the party enjoyed to the utmost the elaborate and appetizing supper which had been provided for them at the famous Fanchère House. There was then a pleasant evening ride of seven miles back to Port Jervis, after which everybody was ready to sleep the sleep of the just.

The next morning Dr. Hunt furnished a sumptuous breakfast in his little Memorial Hospital at Port Jervis, and after the night's refreshing slumber the company did ample justice to the many good things provided by his bountiful hospitality. It was a very informal repast, and the occasion was one of social pleasure which will long remain green in the memories of those who were present. The Hunt Memorial Hospital, which has only recently been erected, although small, is one of the finest and most completely equipped in the State, and its many admirable appointments and appliances were inspected with much interest; after which this pleasant outing came to an end, and all parted well pleased with the success of the seventh special meeting of the Branch.

About two years ago General Newton, Commissioner of Public Works, secured the services of a civil engineer of high repute, Mr. Rudolph Hering, to make a thorough examination of the sewage system of the city, and his carefully prepared and elaborate report—the only complete one on the matter that was ever made, has recently been submitted to the present Commissioner, Mr. Gilroy. In it Mr. Hering makes a detailed statement of the present condition of the sewers, and also expresses his opinion as to the measures that should be adopted for their improvement and the best means of keeping them in good condition. Upon the subject of flushing and cleaning he believes that rainstorms cannot be relied upon for this purpose, and that repeated flushing with properly proportioned quantities of water is required for pent-up sewage. By this process, he says, sewage may not only be kept much cleaner than at present, but stoppages and floodings caused by the accumulation of deposits can be reduced to a

minimum. Deposits become too firmly compacted, he claims, to be carried off by the average storm; while flushing, on the other hand, prevents deposits from accumulating. In other cities, according to the character of the district in which the sewers are placed the periods of flushing vary from once a fortnight to about once a year. In some places automatic flush tanks are used which discharge once or twice a day. The sudden discharge of a large quantity of water seems to him to be the thing desired. In the case of those sewers in the older part of New York which cannot be flushed because their interior surface is rough and irregular, manual labor is the only remedy until they can be rebuilt. Mr. Hering advises that gates should be provided in the main sewers in order to stop the ordinary flow of water for five or six hours before flushing; no other provision being necessary for accomplishing this purpose. The gates could be closed in the morning, and opened in the afternoon. He claims that if all the brick sewers were thus cleansed the yearly expense would be about \$11,000; while at present only about one-twentieth of the brick sewers are cleansed once a year, at an expense of over \$23,000.

Chief Engineer Horace Loomis, in charge of the Bureau of Sewers, in commenting on this part of Mr. Hering's report, has stated that he should be very much pleased to give his device for flushing a trial, but that the expense would be greater than Mr. Hering supposed. "According to his estimate," Mr. Lewis said, "it would cost about \$21,000 a year to clean all the modern brick sewers twice a year and all the pipe sewers four times a year. For the construction of the gates which he recommends, however, the original outlay would be quite large. It would probably cost about \$250 each for the gates and flushing chambers, and as a gate would be required for every thousand feet, this would impose an expense of \$1,250 for each mile of sewer. As there are about 400 miles within the city, the original cost of providing for this manner of cleaning and flushing would be \$500,000, and the interest on that outlay ought to be considered a part of the expense of operation. These figures will indicate that whatever may be done in this direction will have to be accomplished gradually."

Having mentioned one particular sewer which he thought especially adapted to make an experiment of the gate system in, he stated that if on trial it should be found to be successful there, there would be reason to hope that the department might be allowed to extend the system to other parts of the city. He then went on to say that he could foresee more possible dangers from the new system. Whenever sewers were extended through a low-lying district in which the cellars were below the sewer level, he thought a flushing would make things very uncomfortable

for people living above these cellars. There would also have to be special care taken, he said, that the flushing should take place when the tide was just right. Moreover, a shower would be liable to cause flooding when the gates were closed, and he therefore thought that with any such change in the sewer system back-water valves ought to come into general use.

It is certainly a curious circumstance that so soon after the interview with Dr. D. Tilden Brown, referred to in *THE JOURNAL* of September 7th, the Doctor should have committed suicide. On Wednesday night, September 4th, the unfortunate man hanged himself in his barn at Batavia, Ill. A few years ago Dr. Brown was well known to the medical profession in this State and throughout the country. For twenty years previous to 1875 he was Superintendent of the Bloomingdale Asylum, the department for the insane of the New York Hospital, and was regarded as a high authority in mental diseases. In 1875 a New York newspaper began a fierce assault upon the Bloomingdale Asylum because of alleged abuses existing there, and it is said that this attack so affected Dr. Brown that his health failed and his mind became unbalanced. In this condition his wife took him abroad for treatment. His insanity was of a mild form, and in an Edinburgh asylum a partial cure was effected. On their return to America he was placed in an asylum in Illinois, where his wife secured the position of matron for herself, and here what was believed to be the complete cure of the case was brought about. His son, Dr. F. T. Brown, lives in this city.

In an interview published since the suicide Mr. Charles E. Strong, who for the past twenty years has been one of the Board of Governors of the New York Hospital, thus refers to Dr. Brown and his sad history: "He was as competent a superintendent as Bloomingdale ever had. At the time of the exposure of alleged outrages there the confidence of the Governors in his integrity was never shaken. His only fault was that of over-confidence in his subordinates. He was a particularly sensitive man, however, and it was undoubtedly these attacks which made it necessary for him to go abroad for treatment. Since his return to America he has been in constant communication with his friends here. About two weeks ago a New York newspaper printed a sensational story, the substance of which was that Dr. Brown, the old Superintendent of the Bloomingdale Insane Asylum, who had himself become insane in 1875 and gone to Edinburgh for treatment, where it had been supposed by all his friends that he had died, had been discovered living on a farm at Batavia. If Dr. Brown has committed suicide, I believe it was for the reason that this story, in which the saddest portion of his life was reviewed, was called to his attention,

and the shock brought back his old mental affection. He was highly respected in Batavia, where he was practicing medicine with success."

Another of the now often repeated demonstrations of the force of an artificial electric current to destroy life was recently afforded in the dynamo room of the East River Electric Lighting Company in this city, where an experienced electrician, the Superintendent of Construction of the company, accidentally came in contact with the current and was struck dead in an instant. It was an alternating current and its force was in the neighborhood of 1,000 volts, considerably less than it is proposed to use in executing criminals under the new law. The final argument on the question of the constitutionality of this law, a question which involves the disputed power of an alternating current to kill, is about to be held at Buffalo, and this case may have considerable weight in the argument. In the experiments there to be made it is proposed to use an alternating current of from 1,500 to 2,000 volts, and it is contended by the contestants that even this force would not be sufficient to surely and instantaneously destroy life. P. B. P.

#### Multiple Gestation.

*To the Editor:*—The recent death of Mrs. Michael Dress, of Schuylkill Haven, recalls to my mind the following facts concerning her life:

I do not know at what age she was married, but during her marital relations she was the mother of the rather remarkable number of *twenty-eight* children at full term. The record of births I do not recall, but I do know that out of this number there were but two single births—the balance were in twins upon several occasions, triplets twice or three times, and quadruples once. The quadruple birth the children lived to grow up, and one of the number, a female, died from traumatic peritonitis some few years ago. The mother was a large, stout woman, and reached the age of over sixty years. Her habits of life were those peculiar to hard out-door work and plenty of it.

As this case possesses some features worthy of record, I am glad to have possession of the facts in view that the case may be made an item of interest.

I presume it would properly come under the head of "Progressive Uterine Fecundity."

Very truly,

D. W. BLAND, M.D.

Pottsville, Pa., September 17, 1889.

PROF. RAY LANKESTER, who was attacked with serious illness while in Paris, has, under the care of Dr. Faure Miller, now completely recovered and has returned to England.

## MISCELLANY.

THE GOLDEN BELT DISTRICT MEDICAL SOCIETY will hold its Fall Meeting at Salina, Kan., on Thursday next. Sessions at 2 P. M. and 7:30 P. M.

SCARLET FEVER has become epidemic in Birmingham, Eng. The situation is serious. Most of the schools are closed, and the hospitals are so crowded with patients that auxiliary wards must be opened.

THE AMERICAN PÆDIATRIC SOCIETY at Baltimore, elected the following officers: President Dr. J. Lewis Smith, of New York; secretary, Dr. W. D. Booker, of Baltimore; recorder, Dr. William P. Watson, Jersey City; treasurer, Dr. Charles Warrington Earle, of Chicago, and Dr. L. Samuel Holt, member of council.

THE DESTRUCTION OF MOSQUITOES.—*The Microscope* says that Robert H. Lamborn has placed in the hands of Morris K. Jessup, of the American Museum of Natural History, New York, the sum of \$200, to be paid in three prizes of \$150, \$30 and \$20, for the three best essays on the destruction of mosquitoes and flies by other insects. It is suggested that the dragon fly is an active, voracious and harmless "mosquito hawk," and that it might, if artificially multiplied, diminish the number of smaller insect. A practical plan is called for in the breeding of the dragon fly or other such destroyer in large numbers, and its use in the larva, pupa or perfect state, for the destruction of mosquitoes and flies in houses, cities and neighborhoods.

DIPHThERIA EPIDEMIC.—The prevalence of diphtheria in Marion, Ind., has created such alarm that the public schools were ordered closed last Monday for one week. About a dozen deaths have occurred. The point of greatest danger is believed to be passed, but the schools were ordered closed as a precautionary measure.

AN EPIDEMIC of a disease resembling dysentery has been raging near Meadowville, W. Va. Twelve persons have died. About twenty other cases are reported.

JACOB RODGERS died last week at Pittston, Pa., aged 111 years. He was born near Pittsburg, January 1, 1778. He was in the war of 1812, and was wounded at the battle of Lundy's Lane. By his first wife he was the father of fifteen children, and by his second of six. Nine of the twenty-one are living, one of them being 82. Mr. Rodgers had used tobacco for nearly 100 years. Until a few months ago he read without spectacles.

SHELBY COUNTY MEDICAL SOCIETY.—The next meeting of this Society will take place on Monday, October 14, 1889, at the Ray House, Shelbyville, Ind. The following papers will be read and discussed: "Management of Normal Labor, with Particular Reference to the Employment of Antiseptics in Midwifery Practice," by Dr. J. W. Green, Shelbyville; "The Use of Ergot in Labor," by Dr. S. L. Strickler, Boggs town; "Practical Obstetrics," by Dr. John Moffett, Rushville; "Delivery of the Placenta, with Report of Cases of Adherent Placenta," by Dr. M. R. Gilmore, Boggs town; "Management of Shoulder Presentations," by Dr. Edward F. Wells, Shelbyville; "Post-partum Hemorrhage, with Report of Cases," by Dr. J. W. Bowlby, Marion; "Puerperal Eclampsia, with Report of Cases," by Dr. T. R. Rubush, London; "Management of the Perineum, with Report of a Case of Rupture," by Dr. I. W. Trees, Smithland.

## LETTERS RECEIVED.

Dr. M. J. Dudley, Sonoraville, Ga.; Dr. G. L. Morgan, Wichita, Kan.; Dr. S. P. Heilman, Heilmandale, Pa.; Dr. D. A. K. Steele, Chicago; J. B. Lippincott Co.; Philadelphia; Munn & Co., New York; Dr. Landon B. Edwards, Richmond, Va.; Dr. A. L. Hummel, Philadelphia; Dr. G. Betton Massey, Philadelphia; Dr. James H. Jackson, Dansville, N. Y.; Henry Bernd & Co., St. Louis, Mo.; Dr. C. C. Hunt, Dixon, Ill.; J. Walter Thompson, New York; Dr. C. R. Reed, Middleport, O.; Dr. G. L. Collins, Providence, R. I.; Dr. H. Cushman, Stanton, Neb.; Ketteredge & Moran, Ann Arbor, Mich.; Dr. J. W. S. Gouley, New York; Mast, Crowell & Kirkpatrick, Springfield, O.; Evening Bulletin, San Francisco, Cal.; Dr. J. C. Wiesen, Philadelphia; Dr. F. M. Pendleton, Magnolia, Ill.; Dr. B. T. Fisher, Indianapolis, Ind.; Dr. W. Freudenthal, New York; Dr. R. R. Walker, Paris, Tex.; Doliber Goodale & Co., Boston; Dr. Wm. C. Dabney, University of Virginia, Va.; Dr. Dwight L. Hubbard, New York; Dr. Max Thorner, Cincinnati, O.; Dr. J. H. C. Simcs, Philadelphia; Oneita Spring Co., Utica, N. Y.; Roseberry Nutrolactis Co., E. Merck, New York; Dr. Mary M. Cutler, Pomeroy, O.; Dr. I. E. Atkinson, Baltimore, Md.; Surgeon-General John B. Hamilton, Washington, D. C.; J. B. Lippincott Co., Philadelphia; Dr. L. H. Wood, Denver, Col.; Dr. John S. Lewis, Dubuque, Ia.; Dr. K. M. F. Sandberg, Chicago; Dr. R. J. Dungleison, Philadelphia; Ward Bros., Jacksonville, Ill.; Dr. F. M. Thomas, Sannantha, O.; Dr. A. K. Conrad, Portageville, Mo.; Dr. B. F. Hart, Marietta, O.; E. Steiger & Co., New York; Dr. W. H. Geddings, Bethlehem, N. H.; Dr. W. R. Tipton, Las Vegas, N. M.; Dr. Martha C. Holmes, New York; Dr. George A. Dixon, New York; Dr. F. King, New York; Dr. John O. Roe, Rochester, N. Y.; *The Lancet*, London, Eng.; H. Hornfeld, Berlin, Germany; Parke, Davis & Co., Detroit, Mich.; Dr. A. M. Vail, Rock Rapids, Ia.; Dr. Geo. T. Welch, Keyport, N. J.; J. Astier, Paris, France; George Kiel, Philadelphia; I. Haldenstein, New York; Dr. J. Haller, Lanark, Ill.; Lea Bros. & Co., Philadelphia.

*Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 14, 1889, to September 20, 1889.*

Col. Andrew K. Smith, Surgeon U. S. Army, granted leave of absence for fourteen days on surgeon's certificate of disability, by direction of the acting Secretary of War. Par. 1, S. O. 214, A. G. O., September 14, 1889.

By direction of the acting Secretary of War, First Lieut. Freeman V. Walker, Asst. Surgeon, is relieved from duty in the Dept. of Texas, and will, upon the expiration of his present leave of absence, report in person to the commanding officer, Jackson Bks., La., for duty at that station, and by letter to the commanding General, Div. of the Atlantic. Par. 2, S. O. 212, A. G. O., September 12, 1889.

*Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 21, 1889.*

Medical Inspector G. S. Beardsley, granted six months' leave, with permission to go abroad.

Surgeon M. L. Ruth, order granting furlough revoked and placed on waiting orders.

Medical Director Hudson, Medical Inspector Woods and Surgeon Dickinson will continue as President and members of an Examining Board for examination of applicants for the position of Asst. Surgeon in the Navy at San Francisco, Cal., until June 30, 1890.

## ADDRESSES.

### THE CHAIRMAN'S ADDRESS.

*Delivered in the Section of Diseases of Children at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY J. A. LARRABEE, M.D.,  
OF LOUISVILLE, KY.

*Gentlemen:*—Again the bell has struck a warning note upon the horologe of time; again we have assembled for the purpose of contributing our mite to a science which can no longer be called "a conjecture," a science which challenges the admiration of the whole civilized world. Like a "Grand Army of Veterans" we meet around the campfire of the fortieth annual reunion of the American Medical Association. Permit me, then, to greet you as valiant captains of a mighty host of warriors, each bringing the trophies of successful battle with the common enemy of mankind. I see before me those who, amid frosts and snows of a northern winter, have fought the savage foe whose wolfish grasp lay at the throat of the child; those who, beneath a semi-tropical sun, single-handed and alone have fought the pestilence, which walketh in darkness and which wasteth at noonday; those who, along the bold headlands of New England, have met the enemy "upon the storm-swept hill;" those who, upon the fertile plains of our western prairies, have fought long and hard with the hydra-headed monster of the soil. From the North and the South, from the East and the West we meet around the altar of legitimate medicine. Here we renew our obligations to science. Here we pledge anew our friendships and extend our acquaintance. Here, also, we cherish the memory of those who, having rested from their labors, their works do follow them.

The decade just ended has been conspicuous for the commemoration of historic events. Centennial anniversaries have been largely the order of the day, and we have been especially favored in that our meetings have been associated with these pleasant gatherings. Those among us who are so fortunate as to possess a record of revolutionary ancestry are especially congratulated. It is with commendable pride that we revert to the fact, which ought never to be forgotten, that in

the long and perilous struggle for freedom, which laid the foundation of the great American nation, the noble profession to which we belong has always been in the front, not only of pioneer life, but also in true, self-sacrificing patriotism; that the title of Doctor of Medicine shines forth like stars in the emblazonry of our national escutcheon, from Joseph Warren, of Bunker Hill, to Hugh Williamson, of Camden, and from Lexington to Yorktown. But the ground upon which we meet to-day is still more precious to the historian. Not only does the pious, stern and relentless countenance of the Puritan rise up before us, but by the magic touch of the classic pen of our own Longfellow the cold and silent finger of the "skeleton in armor" is pointed backward through the dim vista of the ages.

I well remember that when I was a boy and sat upon the hard wooden benches of a little red New England schoolhouse my sympathies were always aroused by a picture in the leaves of a well-worn history. That picture represented a very small man with a very large hat and a very long staff, and behind him followed seventeen as forlorn and pensive-looking creatures as ever figured in print. It was Roger Williams and his adherents being driven by religious persecution and hatred to seek a home or to die in the wilderness of Rhode Island. It is to this wilderness that we have been invited, and to this wilderness we have come to participate, with a generous and hospitable people, in the celebration of the two hundred and fiftieth anniversary of its settlement. In this history there is certainly food for thought and for congratulation. For thought, that many of the most important advances which have been made in medicine and surgery have been met by persecutions scarcely less vigorous and criticisms hardly less cruel. Old John Talbot, for daring to recommend a new, nauseous and bitter drug for the cure of His Majesty's ague, is here to be remembered; also (within the recollection of living men) the ridicule and professional ostracism, by the erndite editor of a Philadelphia newspaper, of the quackish doings of the Boston doctors in using anæsthetics for surgical operations; and our own Ephraim McDowell would have been driven into the wilderness by foreign persecutors had he not already

been in one. Congratulation, that an enlightened civilization has so far increased our charity that we are enabled to pursue in peace a science which loves truth, invites fact and discards superstition; that we no longer live in dread of a "doctors' mob" against dissection or the gibbet for vaccination. What place, then, more fitting for the burial of professional animosities than this! "Pathists" but poorly become men who are searchers after truth. The broad title of "Doctor in Medicine" should be the only distinction of those who should have no other rivalry than a generous emulation of who can do the best work and best agree.

The reformer is abroad in the land. His presence is felt in all quarters, from the halls of Congress to the lyceum club, in the church, in the political convention, and from "woman's rights" to temperance; on all subjects and on all occasions he "bobs serenely up." It is not strange, then, that medical societies should form no exception to the general rule. In our meetings he seldom contributes to the scientific discussions—never reads a paper. Ethical subjects offer a peculiar and luring attraction, and to avoid complete obscurity he proposes certain changes in established customs, by-laws and constitution, rules and regulations which no one ever found any fault with, and which, in the harmonious course of affairs, few knew to exist. These individuals would change some law at every meeting, and were they to be so fortunate as to enter the heavenly kingdom, would propose to change the laws which regulate the universe itself.

Pediatrics is not a forced specialty in practice. It is not a branch torn from the tree of general medicine and forced to grow apart from the parent stem. The diseases of infancy and childhood, while they possess something (nomenclature) in common with those of adult life, differ so widely in course, duration and consequences that they require especial study. Very many excellent practitioners, appreciating their want of familiarity with infantile symptomatology, decline positively to attend to this class of practice; while many more, less honest in their convictions, continue the practice, although distasteful to them. Pediatrics presents to all an open field and a rich harvest of useful knowledge to all who will become earnest workers. Many of our medical colleges afford no adequate advantages for the medical student to become acquainted with a class of patients who may constitute two-thirds of a general practice. Shall this Section, so important and useful in its labor in the past, so full of work for the future, be united like a set of lectures in one of these colleges, thrown in at the end of a course of obstetrics? An opportunity will be given in the open session at this meeting for you to decide. From this Section the greatest possible good to the general practitioner may be

expected. From its deliberations will originate wise and wholesome laws regulating matrimony, the propagation of healthful children, and the banishment from society of diseases worse than death. These, and many more considerations of equal importance, would seem sufficient plea for the separate existence of a Section in the purpose laid out by its distinguished founder.

Notwithstanding the year has chronicled a very decided advance in infantile therapeutics, the allegory of Addison—of the bridge of human life—still applies: "The pitfalls are still seen to be thickest near the entrance to the bridge." Infantile mortality from preventable causes is far greater than it should be. Your Chairman would venture the suggestion that a standing committee be appointed by the Section, whose duty it shall be to prepare a report upon vital statistics in infancy, said committee to be appointed each year, and said report to be read at a specified time in the meeting of this Section; statistics which shall constitute the basis of this report to be obtained from reliable mortuary reports of cities and towns, and also from the practice of those engaged especially in pediatrics.

In conclusion, gentlemen, it remains for me to express to you my appreciation of the high honor you have conferred upon me in calling me to preside over your deliberations. Esteeming, as I certainly do, the distinction you have placed upon me, I am also keenly sensitive of my own inadequacy. Wholly unversed in parliamentary usages, I beg your indulgence and request your kindly co-operation and assistance in the discharge of the duties which shall devolve upon the chair, that you may not have reason to regret your too partial choice.

## ORIGINAL ARTICLES.

### THE LEGAL RESTRICTION OF MEDICAL PRACTICE IN THE UNITED STATES.

*Read in the Section of State Medicine at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY PERRY H. MILLARD, M.D.,

DEAN AND PROFESSOR OF CLINICAL SURGERY, MEDICAL DEPARTMENT UNIVERSITY OF MINNESOTA; ACTING ASSISTANT SURGEON UNITED STATES ARMY; FORMER SECRETARY MINNESOTA STATE BOARD OF MEDICAL EXAMINERS; EX-PRESIDENT MINNESOTA STATE MEDICAL SOCIETY, ETC.

*Gentlemen:* In reviewing the subject of medical legislation, I am fully cognizant of encroachment of a subject most fertile in theory and suggestion, but quite devoid of illustrative beneficial results; a subject of vital importance to the public and profession, yet receiving but little aid and encouragement from either source in attempts at reforms. The history of medical legislation in this country shows, quite uniformly, that legislatures are quite apathetic when requested to enact

laws regulating medical practice, and are most loth to believe that the best interests of the public are subserved by such laws, many even asserting their belief that all legislation of this character savors of trades unionism. In our attempts at medical reform, the demeanor of the profession has likewise been most discouraging. We concede to all the right of conservatism, but deem it the duty of all good citizens to pass conscientious judgment upon all issues of vital importance in their chosen avocations.

The history of medical legislation is quite instructive. The United States is the only country among civilized nations devoid of adequate medical legislation; even the Chinese are protected by efficient medical legislation, and in our Scandinavian countries the minimum time of study is seven years. The history of medical legislation is most ancient. We ascertain by research that in 1237 the College of Salino instituted a series of regulations to the effect that no one should practice physic who had not studied philosophy three years and physic five, and had obtained the license of the College after undergoing an examination at the end of such period. Very similar regulations were shortly thereafter adopted by the English University, and the standard of medical knowledge and education was thereby considerably raised and a great impetus given to the pursuit of medicine. The first degrees in medicine were granted in 1384. We find by comparison that 150 years before degrees or diplomas were granted, the universities licensed to practice only after the candidates had pursued philosophy three years and physic five, and that 650 years thereafter 70 per cent. of the colleges of the United States only require two courses of lectures and three years of study. Fearing I may be charged with unfairness in my comparative illustration, I will direct your attention to the somewhat suggestive fact that all the colleges of to-day require that our boys be of good "moral character."

The first law regulating the practice of physic was enacted in 1511. The practice of medicine at this time was largely conducted by the ignorant portion of the artisan class. Medical degrees, however, were held in high esteem by the people. The progress of medicine in the seventeenth century has been ably pictured by Macaulay in his "History of England," vol. 1, page 310. "Medicine," he says, "which in France was still in abject bondage, and afforded for Mollière an inexhaustible subject for ridicule, had in England become an experimental and progressive science, and every day made some new advance, in defiance of Hippocrates and Galen. The attention of speculative men had, for the first time, been directed to the importance of sanitary police. To that period belong the chemical discoveries of Boyle and the first botanical re-

searches of Sloan. One after another, phantoms which haunted the world through ages of darkness, fled before the light, and astrology and alchemy became jests. Upon research I find that in ancient times medical legislation and higher medical education progressed hand in hand. Upon research, I am unable to find that any court or legislative body in the British Isles or Continental Europe ever questioned the propriety of effective medical legislation.

The experience of the various States in the United States is, however, suggestive. Previous to the present decade, no State in the Union possessed an efficient medical practice act. The laws in existence in the few States possessing the same were too inefficient to merit mention at this time. The most efficient of them only required the filing of a copy of a diploma with some office of record, generally a clerk of court or county clerk. Many of these diplomas were purchased outright, as was afterwards proven in the famous Buchannan diploma cases.

The first State to pass a law based upon rational principles was North Carolina. The efficiency of this act was practically emasculated, as the bill possessed no penalties. Among the earlier acts of the present decade were what was known as the Illinois Act. This act provided for the issuance of a license by submission of a diploma from a school of medicine recognized by the board. This act was, in my opinion, quite as radical as could have been enforced at the time of its enactment. The essential features of this bill were copied in the subsequent practice acts of Minnesota, from 1882 to 1887, Missouri, Iowa and West Virginia. The practice acts of the above-named States were retroactive in their features or provisions, and were applicable to upwards of 15,000 physicians. The gentlemen entrusted to execute the law in these States are the only persons that can actually recognize the obstacles and intolerable embarrassments encountered in the execution of the act in the above named States. We received most captious criticism and encountered formidable opposition from the sources we least expected, namely, the profession itself. This criticism and opposition did not come from the narrow-minded cynic alone, but, to the shame and disgrace of the profession, from a large number of our medical institutions, some of which, we regret to mention, were manned by men of eminence and great learning, but had carelessly, for financial reasons only, given cognizance to an opposition to a reform that was entitled to an undivided support and encouragement from every member of the profession from the Atlantic to the Pacific. Of the nine attempts to repeal the present Minnesota Medical Practice Act at the last session of the legislature of Minnesota, a majority of the professed amendments emanated directly from the medical colleges

themselves. The profession, gentlemen, is not cognizant of the great trials encountered in bringing about a fair degree of efficiency of the present inefficient acts. To John H. Rauch belongs the greatest credit in making the so-called Illinois Act efficient in different States. He is the true father of the coming reform, and we are only following in his footsteps. His influence in this matter has been most potent for good, and has directed the attention of both the profession and public of the great need of the present attempted reform. We trust he may be spared to witness a practical application of his labors. The States possessing quite ideal medical practice acts at present are, Minnesota, Montana, Virginia and North Carolina. The Minnesota Act is superior to that of the other States in that it requires that all persons desiring a license to practice shall have taken at least three courses of lectures of not less than six months' duration each. These requirements, in addition to the examination, make a tolerable safeguard for the public. In the future legislation by different States, I believe the profession can safely incorporate the main features of this act in their attempted legislation. It was drafted by me after five years' experience as executive officer of the former Minnesota Practice Act, and two years' successful operation in Minnesota has proven its merits. In the last two years this board has examined ninety-nine applicants for a license to practice and rejected thirty-five. All persons graduated since 1886 must furnish evidence of having attended three courses of lectures of not less than six months' duration each. As a result of this law, the sixty-four physicians that have been licensed to practice in Minnesota the last two years are nearly all graduates of McGill, University of Michigan, University of Pennsylvania, Chicago Medical College, and University of Minnesota. As an illustrative comparison, under the old Minnesota Act, which was the same as the present acts of Illinois, West Virginia, Missouri and Iowa, I licensed 146 physicians in 1885, and 280 in 1886, while the present board licensed sixty-four physicians from July 1, 1887, to July 1, 1889.

As a result of efficient medical legislation Minnesota possesses a smaller ratio of physicians to the population than any State in the Union. Instead of one physician to every 750 inhabitants, the last medical census shows but one to every 1,300. Through the courtesy of the Secretary of the Minnesota Board, I am permitted the first public announcement of these figures. I may state, however, that they are not made public with a view of promoting emigration. It is a pleasure to announce that both the profession and the public are quite uniformly supporting the law.

The profession is at present awakening to the

necessity of efficient medical legislation. The fields are fertile and the harvest shall be plentiful; the handwriting is on the wall, and the interpretation is easily read. The people have awakened to the fact that there are twice as many practitioners of medicine in this country as are commensurate with its legitimate wants. The number being as one to every 750 in the United States; one to every 1,660 in Hungary; one to every 1,639 in Italy; one to every 2,932 in Austria; one to every 3,225 in Germany; one to every 3,780 in France, and one to every 7,909 in Sweden. The great number of medical men in this country makes competition very sharp, and, in consequence, people too frequently suffer from dishonorable practices. My own observation teaches me that the people of this country take too many drugs; this is particularly true of the American born citizen. The people are also cognizant of the fact that the methods of medical instruction in this country is deserving of severe censure.

The report of the Commissioner of Education of the United States shows that in 1886 there were but \$2,671,490 in the grounds, buildings and apparatus of the 130 medical colleges of the United States. That the productive funds of the same were \$266,193, and the annual income from investments only \$22,000. Less than a dozen of these schools are in any way endowed. How best to prevent the flooding of this country with half educated medical men, is a vital question to both the public and profession at this time. After years of experience and observation in this country and Europe, I can unhesitatingly assert my conviction that our only remedy lies in efficient medical legislation. We are well aware that many of our medical colleges are honestly endeavoring to raise the standard of acquirements, and that in consequence their students have decreased in numbers and they have received but little encouragement at the hands of the profession itself. I believe that the adoption of a medical practice act in each State, possessing the features of the bill favored by the Commission on Uniform Medical Legislation, of which I have the honor to be Chairman, will afford the people and an overcrowded profession the much desired relief. This committee recommends to this Association for consideration, a bill calling for a State Board of Examiners to be appointed by the governor. A bill requiring that all persons commencing practice shall undergo an examination, at the hands of said board, that is both scientific and practical, but of sufficient severity to test the candidate's fitness to practice medicine. Before being allowed to compete for a license by examination, the candidate must submit a diploma from a recognized medical college that requires a preliminary entrance examination upon the following named branches, to-wit.: English grammar,

composition, geography, history, arithmetic, algebra, physics and the natural sciences, together with at least one of the following languages: Latin, French or German. In addition a curriculum requiring attendance upon at least three full and regular courses of lectures before graduation, of not less than six months' duration each.

A bill providing that license may be refused or revoked for chronic inebriety, criminal abortion and gross unprofessional conduct. Also, that all licenses be a matter of public record by being recorded with a clerk of court or some officer of public record.

I believe, gentlemen, that the best interests of the public and profession will be subserved by efficient legislation, as recorded by this committee. Opposition at this time is evidence of a selfish motive, or a fatal weakness, if emanating from any special school of practice. Experience has proven that the so-called mixed boards have worked in harmony in the different States possessing the so-called Illinois Act, or rather the act recognizing a diploma as entitling the possessor thereof to registration. If a bill is passed by the different States calling for an examination of all applicants for a license, I can easily foresee a radical change in the character of instruction afforded by a majority of the medical colleges of this country. The reputation of colleges will not depend so much upon the number of students as upon the actual character of the instruction afforded the students. Such is the case in Europe, and should be the case in America.

In conclusion, gentlemen, let me bespeak for our noble calling a higher appreciation at the hands of the public. Our destinies are the product of our own action. I believe the future can be made more desirable than has been the past; as we sow, so shall we reap. I know it is in our power to afford the public a better profession, and realize that the best interests of the public will be subserved thereby. Let us endeavor to reduce the number of medical colleges, and, at the same time, raise the standard of instruction afforded.

DR. N. S. DAVIS, of Chicago, said that the subject of the paper was a most important one. The laws should be sufficiently harmonious in the various States to enable one, after once qualifying, to practice medicine in any State. They would be eligible to a license for practice in any other State without another examination. The objectionable feature of the Illinois State law is the fact that the diploma itself enables one to obtain license to practice. The medical colleges should be made to rival each other in the character of the work done by them. The student endeavors to get through his college work in the shortest possible time and at the least expense. From one-half to two-thirds of the students try to find

the cheapest and easiest college. Teaching and licensing should be in separate hands. A high grade of preliminary education should be demanded. The State Board should be appointed by the governor with the concurrence of the senate.

DR. GIBON, U. S. N., was of the opinion that preliminary education is the most important consideration.

DR. SMART, U. S. A., accorded with Dr. Davis regarding the requirements preliminary to practice.

DR. SCAMMON, of Tennessee, agreed with Dr. Davis in the main, but thought the board should not be appointed by the governor, but be elected by the physicians.

AN ACT ENTITLED, AN ACT TO REGULATE THE PRACTICE OF MEDICINE AND SURGERY, TO LICENSE PHYSICIANS AND SURGEONS, AND TO PUNISH PERSONS VIOLATING THE PROVISIONS THEREOF.<sup>1</sup>

*Be it enacted by the Legislature of the State of—*

SECTION 1. The Governor shall appoint a Board of Examiners, to be known as the State Board of Medical Examiners. Said Board shall consist of nine members. The appointees shall be persons of recognized professional ability and honor. The term of office of said Board shall be three years, or until their successors are appointed; *provided*, however, that the members thereof shall be divided into three classes, each class to consist of three persons. The first class shall hold office under said appointment for one year, the second for two years, and the third for three years from the date of their appointment. It is further provided that no member of said Board shall serve more than two terms in succession. No member of any college or university having a medical department shall be appointed to serve as a member of said Board.

SEC. 2. Said Board of Medical Examiners shall elect a President, a Secretary and a Treasurer. It shall have a common seal, and the President and Secretary shall be empowered to administer oaths in taking testimony upon any matter pertaining to the duties of said Board. Said Board shall hold meetings for examinations at the Capitol Building of this State the first Tuesday of January, April, July and October of each year, and at such other times and places as the Board shall deem expedient. Said Board shall keep an official record of all its meetings; also an official register of all applicants for examination for a license to practice medicine and surgery in this State. Said register for license shall show the name, age and last place of residence of each candidate, the time he or she has spent in medical study, in or out of a medical school, and the names and locations of all medical schools which

<sup>1</sup> Copy of Act submitted by Committee on Medical Legislation, and read in the Section of State Medicine at the Fortieth Annual Meeting of the American Medical Association June, 1889.

have granted said applicant any degree or certificate of attendance upon lectures in medicine. Said register shall also show whether such applicant was rejected or licensed under this Act. Said register shall be *prima facie* evidence of all matters therein contained.

SEC. 3. All persons hereafter commencing the practice of medicine or surgery, in any of its branches, in this State, shall apply to said Board of Medical Examiners for a license so to do. Applicants for examination shall be divided into three classes, to wit: Persons graduated from a legally chartered medical school not less than five years before the date of application for a license; second, all other persons graduated from a legally chartered medical school, and medical students taking a regular course of medical instruction. Applicants of the first class shall submit to examination upon the following named branches, to wit: *Materia medica* and therapeutics, obstetrics and gynecology, practice of medicine, surgery and surgical anatomy. Those of the second and third classes shall submit to examination upon anatomy, physiology, chemistry, *materia medica* and therapeutics, histology and pathology, hygiene, practice of medicine, surgery, obstetrics and gynecology, diseases of eye and ear, medical jurisprudence, and such other branches as the Board may deem advisable. The questions for examination of applicants of the first and second classes shall be the same in branches common to both. Said Board shall not license graduates of later date than January 1, 1890, until satisfactory proof is furnished that the applicant has studied medicine and surgery three years before graduation; attended at least three full courses of medical lectures, of not less than six months' duration each; is of good moral character and over twenty-one years of age. Applicants of the third class, upon completion of two full courses of lectures, of not less than six months' duration each, can be examined upon the following named branches, to wit: Anatomy, physiology, chemistry, histology and pathology, and *materia medica* and therapeutics. If said examination is satisfactory to said Board, it may issue a certificate that the applicant has passed a final examination in these branches. All examinations shall be both scientific and practical, but of sufficient severity to test the candidate's fitness to practice medicine and surgery.

SEC. 4. All examinations shall be in writing, unless otherwise requested by applicant. In all oral examinations the questions and answers must be of a fundamental character and, except in therapeutics, such as can be answered in common by all schools of practice. If said examination is satisfactory the Board shall, provided that the applicant shall be at the cost and trouble of securing the presence of such dean or president, and that this shall not interfere with the

regular conduct as to time and place of the examination, issue a license entitling the applicant to practice medicine in this State. The votes of all examiners shall be by yes or no and written, with their signatures, upon the backs of the examination papers of each candidate for the respective branches. A license shall not issue unless the applicant passes a satisfactory examination on at least two-thirds the branches required by this Act. Said examination papers shall be kept on file by the Secretary of said Board, and shall be *prima facie* evidence of all matters therein contained. All licenses shall be signed by the President and Secretary of said Board, and shall be attested by the seal thereof. The fee for examination shall be \$15 for each applicant of the first and second classes, and \$20 for each applicant of the third class. It shall be paid to the Treasurer of the Board and applied towards defraying the expenses thereof.

SEC. 5. The Board may, by a unanimous vote, refuse to grant or revoke a license for the following named causes, to wit: Chronic and persistent inebriety, the practice of criminal abortion, or for publicly advertising special ability to treat or cure diseases which, in the opinion of said Board, it is impossible to cure. In complaints for violating the provisions of this section the accused person shall be furnished with a copy of the complaint and given a hearing before said Board, in person or by attorney, and can finally appeal from the decision of said Board to the appointing power thereof.

SEC. 6. The person so receiving said license shall file the same, or a certified copy thereof, with the Clerk of the District Court in and for the county in which he or she resides, and said clerk of the court shall file said certificate, or copy thereof, and enter a memorandum thereof, giving the date of said license and the name of the person to whom the same is issued, and the date of said filing, in a book to be provided and kept for that purpose; and said clerk of the court shall each year furnish to the Secretary of said Board a list of all certificates on file in his office, and upon notice to him of the change of location or death of a person so licensed, or of the revocation of the license granted to such person, said clerk shall enter, at the appropriate place in the record so kept by him, a memorandum of said fact, so that the records so kept by said clerk of the court shall correspond with the records of said Board, as kept by the Secretary thereof. In case a person so licensed shall move into another county of this State, he or she shall procure from the clerk of the court a certified copy of said license, for which no charge shall be made, and then file the same with the Clerk of the District Court in the county to which he or she shall so remove. Said clerk shall file and enter the same with like effect as if the same was the original license.

SEC. 7. This Act shall not apply to commissioned surgeons of the United States Army, Navy or Marine Hospital Service, to physicians or surgeons in actual consultation from other States or Territories, or to persons temporarily practicing under supervision of an actual medical preceptor.

SEC. 8. Any person shall be regarded as practicing medicine or surgery, within the meaning of this Act, who shall append the letters M.D. or M.B. to his or her name, or repeatedly prescribe or direct, for the use of any person or persons, any drug or medicine or other agency for the treatment, cure or relief of any bodily injury, infirmity or disease. This Act shall not apply to dentists or midwives in the legitimate practice of these branches exclusively.

SEC. 9. Any person practicing medicine or surgery in this State without first having obtained the license herein provided for, or contrary to the provisions of this Act, shall be deemed guilty of a misdemeanor and, upon conviction thereof, shall be punished by a fine of not less than \$50 or more than \$100, or by imprisonment in the County Jail for a period of not less than ten or more than ninety days, or by both fine and imprisonment. Justices of the peace and the respective municipal judges shall have jurisdiction of violations of the provisions of this Act. It shall be the duty of the respective county attorneys to prosecute violations of the provisions of this Act.

SEC. 10. All Acts or parts of Acts now existing not in accordance with the provisions of this Act, are hereby repealed.

SEC. 11. This Act shall take effect and be in force from and after its passage.

Signed :

*Com. on Uniform Medical Legislation of the American Medical Association.*

## ON THE CONNECTION OF CHRONIC DISEASES OF THE UPPER AIR-PASSAGES WITH ABDOMINAL HERNIA.

*Abstract of a paper read in the Section of Laryngology and Otology at the Fortieth Annual Meeting of the American Medical Association, held at Newport, R. I., June, 1889.*

BY W. FREUDENTHAL, M.D.,

PHYSICIAN TO THE GERMAN POLIKLINIK, N. Y.

If it be true that "necessity is the mother of invention," then no period was more suitable for that great invention, the laryngeal mirror, than the present one.

The tendency of modern civilization is to imprison us closely within the walls of our cities and houses. As a result we find an increased tendency to the development of diseases of the

air-passages, together with various less conspicuous sequelæ. As an example of these I may mention *abdominal hernia*. As regards the origin of ruptures caused by nasal affections, I made the following remarks before the German Medical Society of New York (*Zur Aetiologie der Unterleibsbrüche*, *N. Y. Med. Presse*, Oct., 1888): "If primarily we consider this question from a purely theoretical standpoint, nothing is easier than to prove the *possibility* of the origin of a hernia from an affection of the nose, in the same way as, long ago, it has been considered proven as the result of a bronchial affection. The force of the cough, pressing the abdominal contents against already non-resistable parts of the lower abdomen, increases the susceptibility to the formation of a hernial sac, and afterwards a hernia, and this is accomplished by intensified and oft-repeated action of the intra-abdominal pressure."

Intra-abdominal pressure has played a great rôle in former years, especially in Germany. Modern surgeons have again rescued it from oblivion; into which it seemed to have fallen. Already in Rust's "*Handbuch der Chirurgie*" (vol. 8, pp. 360 ff.) we read that even when a hernia at last suddenly appears, after a more or less violent exertion, still its origin has been prepared by oft-repeated pressure of the contents through a slow but long continued dilation of the peritoneum.

A further practical use of this idea was made by Friedberg (*Vierteljahrsschr. f. prakt. Heilk.* Prag. 1864), who showed the connection between the origin of herniæ and congenital phimosis in boys. The patency of the processus vaginalis peritonei can not, according to him, be a sufficient cause for the origin of herniæ, as this has been found open in many cadavers without a hernia being present. Still, however, this can give the predisposition which only awaits some exciting cause to produce a hernia. This idea of the origin of a hernia from a marked case of phimosis has, of late, been taken up and is held by quite a number of writers, especially by Kempe, Osborn (who also gives an explanation for the greater frequency of right-sided herniæ in infants), Hans Schmid, and Karewski. Now, compare the pressure upon the abdominal contents induced by a phimosis, with that of chronic diseases of the upper air-passages. "When the nasal secretion is normal, the pressure upon the abdominal contents is so slight that it need not be regarded. When, however, . . . pathological changes take place . . . then the expiratory straining to remove the pent-up secretions increases with the constant and ever changing inability to get rid of it." [See above cited paper.] The expiratory efforts must, therefore, become very strong and continuous. A man with hypertrophy of the turbinated bodies, or with a nasal catarrh, or with a strong pharyngitis granulosa, will hawk, clear his throat

and blow his nose under certain conditions all day long; or, in other words, he will constantly increase the intra-abdominal pressure. A child with a phimosis will do this at the most once every hour and, as I think, in a manner relatively much weaker.

If we examine this theory somewhat more closely, the question which everybody naturally will ask is this: Is there a greater frequency of herniæ in countries where nasal diseases abound? The *N. Y. Med. Record* answered this in the negative, and affirmed that in Germany 82 out of 1,000 conscripts are rejected on account of hernia, in France 65, in Italy 76, while in the northern army only 50 were not taken on account of hernia, although nasal diseases in the United States are extraordinarily common. I refuted these statements by publishing complete statistics of the Austro-Hungarian monarchy, as a substitute for the German, from whom statistics could not be obtained, and came to the conclusion that *the ratio of North America, a country much troubled by nasal diseases, to Austria, much less infested with them, is as 50 to 14. In other words: Hernia is in the United States three and a half times as frequent as in Austria.*

Reasoning from analogy I conclude that in Germany 82 out of 1,000 are not rejected on account of hernia. I shall to-day give you the contents of a table to which my attention was kindly called by the director of the Kaiserliches Gesundheitsamt in Berlin.

It is as follows (Veröffentl. des K. Gesundheitsamtes, 1887):

Year.	Were examined in the Departments of the 1-15th Army Corps.	Rejected, ratio per 1,000.
1876	789,054	128.2
1877	782,482	114.1
1878	822,412	105.6
1879	857,374	110.0
1880	875,480	109.3
1881	864,812	90.1
1882	851,801	85.8
1883	866,572	78.7
1884	884,250	76.7
1885	900,849	74.3

Average for the ten years, 96.6.

According to this average, therefore, there were rejected out of 1,000 conscripts, on account of *physical and mental defects of all kinds, altogether 96.6*; in the last four years (1883-1886) even less than 80. That we, therefore, should meet with such a high average (as 82) for the ruptured alone, is by no means correct. In my opinion the proportion ought to be even more favorable than in Austria; for, as a statistical report of the Royal Bavarian Ministry of War of the year 1883 shows (Zeitschr. des K. Bayerischen Statist. Bureau, München, 1884), there were rejected, "on account of infirmities of the abdomen (mostly ruptures)," 1.4 per cent., or 14 per 1,000. If we subtract the less frequent other

abdominal diseases, we get for herniæ alone a number that is decidedly below 14. As these proportions in the other parts of Germany are alike, perhaps even better, we may conclude, with a probability bordering on certainty, that also in Germany, in accordance with the less frequent occurrence of nasal diseases, herniæ are found only one-third or one-fourth as often as in the United States, the country of nasal diseases, *κατὰ, ἐξ ὀφί' v.*

Concerning Italy and France, I have received, through the kindness of both consulates at New York City, more accurate data.

In Italy, where people do not suffer much from nasal diseases, the figure was said to be 76. In reality the conditions are as follows:

Males of 20 years rejected from military service for abdominal hernia:

Year.	Number of those called, exclusive of those rejected for defects of stature.	Rejected for hernia.	Ratio per 1,000.
1858	250,699	4,052	16.2
1859	270,304	4,282	15.8
1860	224,340	4,401	18.0
1861	254,867	4,264	16.7
1862	273,664	4,506	16.5
1863	303,423	5,080	16.7
1864	297,742	4,796	16.1
1865	304,550	5,026	16.5
1866	317,031	5,260	16.6
1867	301,769	5,129	17.0

Average for the 10 years, 16.61.

France also has not, as was affirmed by the *Record*, 65 per 1,000, but only the following figures:

Ratio per 1,000: Year 1879, 23.2; 1880, 22.1; 1881, 21.3; 1882, 22.3; 1883, 22.9; 1884, 22.7; 1885, 23.2; 1886, 24.1; 1887, 23.2; 1888, 23.9; average, 22.89.

Thus we find the relations exactly as we expected to find them. In Italy, where, at least as far as I know, nasal diseases are less frequent than in France, out of 1,000 conscripts 16.61 are rejected on account of hernia; in France, on the contrary, 22.89. As these data furnish another proof for our theory, I could not omit bringing them in addition.

As you are perhaps aware, I furthermore tried to prove that where *nasal diseases decrease, the number of ruptures must also be diminished.* I based my statements especially on the results of the excellent investigations of Bryson-Delavan (*N. Y. Med. Journal*, November 12, 1887), who, in accordance with the experience of Zuckerkandl, E. C. Morgan, F. Donaldson, Jr., J. N. Mackenzie and others, has proven that among primitive types deformities of the septum are very rare. On the other hand I showed that these races, at the same time, have but very rarely a hernia, and I called attention to the report of the Provost Marshal-General, that none of the 121 Indians drafted in the last war had a hernia,

and none nasal trouble. These conclusions were, according to my knowledge, opposed by nobody.

Not quite the same happened as to the third question at issue. I finally tried to show that just those people are especially prone to hernia who are least exposed to inclement weather, leading a sedentary life, and who surely have not to carry or to lift heavy burdens. In support of my affirmation I then cited the report of the Provost Marshal-General again (Statistics, Med. and Anthropological, of the Pr. M. Gen.'s Bureau, etc., by J. H. Baxter, Washington, 1875).

In this report we have a tabulated statement of the frequency with which hernia occurs among men engaged in seventy-five varieties of occupations. The smallest percentage is found among soldiers, namely 28.8 per 1,000. Next to them come the tanners and curriers, coppersmiths, students, iron-workers, etc. The latter (iron-workers) show the very interesting number 32, while inn keepers, whose occupation, in proportion to these, can be called an extremely easy one, reach the highest point, namely 101.5 per 1,000. To the same category belong editors, engravers and others, whose percentages range from 95 to 98 per 1,000, and who are by no means as much strained physically as soldiers, coppersmiths, sailors and the like. Tanners and curriers show the number 29.4, while teachers have almost twice the number, viz: 56.6; and dentists, who remain indoors almost the whole day, show even 79. From these data I thought myself correct in drawing the conclusion that people who, through some special kind of occupation, are apt to acquire a post-nasal catarrh, or other diseases of the upper air-tract, are more subject to hernia than others.

To this Dr. Schapringer, in a review published in the *Monatsschr. f. Ohrenheilkunde*, Jan., 1889, replied that people suffering from hernia at the time of selection of their trade never elected to become smiths or the like, but rather engravers, etc. It would, therefore, be the hernia that created the engraver, and not vice versa, the business of an engraver that produced a hernia. Dr. Schapringer, furthermore, thinks that the above tables are of a doubtful value as long as they do not contain details about the first appearance of the herniæ. Now, gentlemen, I can not fulfil his desire, nor do I even think it necessary, as we have statistics about the time of the first appearance of a hernia in great abundance.

According to consonant investigations made by the most prominent writers on this subject (Malgaigne, Cloquet, Kingdon, Wernher, Albert, etc.), it is stated that in males hernia occurs most frequently between the thirtieth and fortieth years of life. What does this fact mean? It teaches us the following: A young man, after having chosen his occupation, which, as a rule, takes place in his twentieth year, or even before that time, and after having followed this occupa-

tion say for ten years, certainly shows by this time the primary effects of such occupation. A soldier, a coppersmith or an iron-worker will have developed his whole muscular system completely by this time—he will rarely show a tendency to catarrh; hence a greater rarity of herniæ. A tailor or an engraver, on the other hand, you will be able to recognize easily from the debility of his constitution. *He has* already, especially in a climate favorable to it, a post-nasal catarrh, hypertrophied mucous membranes in the nose, etc., etc.; and he has *also*, in a proportion by far surpassing the other occupations, hernia. We see, therefore, that it is the occupation which creates the hernia, and not vice versa.

Allow me to mention briefly two more facts in corroboration of this. I have before demonstrated that from the soldiers of the German army, in spite of their hard physical training, the average of those rejected for hernia is not more per year and per 1,000 than 1.05. As I, however, know now—my tables, I am sorry to say, are not so complete as to be published—the proportion is such, that with the increasing age of service the frequency of hernia decreases. Thus we see that bodily straining, gymnastics, out-of-door exercises, etc., can be considered as the *best prophylactics against hernia*.

It was, furthermore, said that in mountainous regions ruptures are more common than in low countries, and this supposition was based on the belief that the labor in ascending the mountains must increase their frequency. The only author whom I am able to cite on this subject is no less an authority than Malgaigne. According to his statements, however, in France the reverse is the case, since just in the mountainous parts ruptures are infrequent, while they are quite common on large plains and *on the shores of the rivers*. We see, therefore, that just where the humidity of the climate is able to cause many nasal troubles, again the herniæ are increased in frequency.

According to my personal experience, which, however, was not exactly directed to this question, I can only say that I have seldom seen so few herniæ as I met while in mountainous regions.

Another question to which I would allude is this: How is it that herniæ are more common in males than in females? The explanation which I have to offer is that while the intra-abdominal pressure is increased in men and women by coughing, the efforts are more violently performed in the case of the former.

In view of all these proofs which I advanced, I hope you will find some truth in my theory, and I shall not try your patience with enumerating a number of less important facts which are in favor of this theory. In concluding my paper, which I have read upon the kind invitation of your Secretary, allow me only to collate the results of my observations up to date:

1. Of 500 ruptured, *ad hoc*, examined by me (*Monatsschr. f. Ohrenheilk.*, November, 1887, f. f.) there were found 143 with strong diseases of the upper air-passages that made surgical interference absolutely necessary.

2. Among about eighty members of a family also examined by me (*loc. cit.*), almost all had diseases of the upper air-tract, and one-third had herniæ.

3. Where nasal diseases are less frequent, there, as we have seen, also less herniæ are found (see Indians).

4. According to the frequency of diseases of the upper air-passages, hernia was found, of each 1,000 conscripts in the United States, in 50; in France, in 22.89; in Italy, in 16.61; in Austro-Hungary, in 14.09, and in Germany probably in even less than 14 per 1,000.

5. Hard physical work, ascending mountains, lifting of heavy loads, etc., never give the *pre-disposition* to herniæ; but, on the contrary, such occupations which involve diseases of the upper air-passages.

6. In women herniæ are rarer than in men, on account of the weaker stress used in pressing down the intra-abdominal contents during the act of hawking, clearing the throat, and the like.

## DIAGNOSIS AND TREATMENT OF ABSCESS OF THE ANTRUM.

*Read before the Section of Laryngology and Otology, at the Fortieth Annual Meeting of the American Medical Association, at Newport, June, 1889.*

BY J. H. BRYAN, M.D.,  
OF WASHINGTON, D. C.

The antrum is that triangular-shaped cavity in the superior maxilla, sometimes found extending into the malar bone forming a second cavity. It is lined by mucous membrane continuous with that of the nose, and it is occasionally thrown into folds forming partial septa, a fact of considerable clinical importance. It varies in size according to the age and sex of the individual, being small in children, and larger in the male than in the female. It diminishes in size in old age and after the loss of the teeth.

Of the surgical affections of the antrum, suppurative inflammations play the most important part. Until within recent years abscess of the antrum was regarded as rather an uncommon affection, but we now know that it exists much more frequently than was formerly supposed. It occurs generally after the second dentition; although there is one case recorded by P. B. Pedley,<sup>1</sup> of a girl 8 years of age, where the abscess was due to caries of a temporary canine tooth.

Among the causes of abscess of the antrum may be enumerated: 1. traumatism; 2. the acute

infectious diseases, such as measles scarlet fever and smallpox; 3. syphilis; 4. an extension of the inflammation from the lining membrane of the nose; 5. extension of the inflammatory process from the suppurating pulp of a tooth resulting from dental caries. Authorities differ as to the most common of these causes. Zuckerkandle, for example, believes that it is more often due to an extension of the inflammation from the nose; while others regard disease of the teeth the principal factor in the etiology. I am of the opinion that the form of inflammation of the antrum characterized by a sero-mucous secretion, and known as *hydrops antri*, is the result of an extension of a catarrhal inflammation of the nose. On the other hand, that form which is more chronic in character, and is accompanied by a mucopurulent secretion, is the result of an extension from the teeth.

The under surface of the antrum is separated from the alveolar process by a thin lamella of bone, which is formed with the development of the permanent teeth; occasionally, however, it is absent, and the roots of the teeth are then likely to extend into the antral cavity. Its floor is in close relation to the roots of the first and second molar teeth; and when the cavity is unusually developed the roots of the first and second bicuspid teeth are brought in contact with it. Lying in such close proximity to the floor of the maxillary sinus, the teeth when diseased are likely to transmit the septic process there, and set up a suppurative inflammation.

The symptoms of this affection vary with the intensity of the inflammation. In a few cases there is distension of the walls of the superior maxilla and swelling of the cheek of the affected side; pain in the infra-orbital region, and at the inner angle of the orbit; tenderness on pressure over the canine fossa, and occasionally a crepitating sensation imparted to the fingers, due to a springing of the distended walls of the antrum; a narrowing of the field of vision, due to pressure on the floor of the orbit, a symptom, according to Ziem, much more frequently associated with affections of the ethmoid cells, and a valuable point in the differential diagnosis between abscess of the antrum and of the ethmoid cells. In some cases there is a discharge of fetid pus from the nose, generally unilateral and of long standing. Long continued secretions of pus from the nose, especially when confined to one side and associated with caries of the molar teeth, should always direct our attention to the antrum as the source of the trouble. A suppurative inflammation of the nose is an extremely rare affection. Stoerk has described such a disease, occurring as an epidemic among the Gallician Jews.<sup>2</sup> It may, however, occur from infection, as for example, from gonorrhœal poison.

<sup>1</sup> Lancet, Feb. 16, 1889.

<sup>2</sup> Krankheiten des Kehlkopfes, p. 161.

There are four possibilities, after eliminating wounds, and inflammations following the acute exanthemata that may give rise to pus in the nasal chambers: 1. foreign bodies, including nasal polypi; 2. diseases of the bones; 3. secretion of pus from the antrum of Highmore; 4. secretion of pus from the frontal sinus and from the anterior ethmoid cells. The secretions from the anterior ethmoidal cells may enter the middle meatus, along with those from the frontal sinus, through the infundibulum, while the secretions from the posterior cells find their way into the pharynx along with those from the sphenoidal sinus.

If the pus should continue to flow after the removal of the polypi, or foreign body, we are then likely to have either an abscess of the maxillary sinus, of the frontal sinus, or of the ethmoid cells. Occasionally it is difficult to differentiate between these, for in each case pus is found in the middle meatus extending along the inferior border of the middle turbinate bone. When this body is sufficiently contracted, which can be accomplished by an application of a 20 per cent. solution of cocaine, the middle meatus will be brought into full view, and pus found in the hiatus semi-lunaris. If it is not possible to bring about the contraction of this body by cocaine, then the hypertrophied or swollen tissue should be destroyed by means of the cantery, or chromic acid. The opening of the frontal sinus will be found just below and in front of the ostium maxillare in a funnel-shaped depression—the infundibulum. Owing to the close proximity of these two openings it is very difficult to discover from which the pus flows. Hartmann, of Berlin, has suggested the following device to ascertain the source of the secretions: After drying the parts thoroughly with absorbent cotton, he drives a blast of air through the affected nostril by means of a Politzer air-bag. By this procedure he claims to be able to aspirate the pus from the sinus and thus discover its source. Another point in the differential diagnosis is that abscess of the maxillary sinus is of comparatively frequent occurrence, while that of the frontal sinus is rare.

The most positive means of differentiating between these two affections, is by making an exploratory puncture, as suggested by Moritz Schmidt.<sup>3</sup> He places a small pledget of cotton saturated with a 20 per cent. solution of cocaine under the inferior turbinate body, about its middle, and allows it to remain in until the parts are thoroughly anæsthetized; then raising the end of the turbinal body, he pierces the thin wall of the antrum with a sharp-pointed and curved syringe. The point of the instrument should be not too fine, so that it will bend or break when making the puncture. There is no pain following the operation and it is entirely devoid of danger. This

little instrument should be employed in all doubtful cases, and its use will, I think, tend to prove that the affection is much more common than is generally supposed. The indications for treatment are to let out the pus and drain and disinfect the cavity until the inflammation subsides. If the abscess should point anywhere it should be evacuated at that place.

A great deal has been written recently with regard to the surgical treatment of these cases, and it is interesting to note the tendency on the part of modern surgeons to deviate from the well-tried practice that has stood for nearly a century, and to return to the original suggestion of John Hunter, and the practice of Jourdain—to evacuate these abscesses through the nose.

For nearly a century the practice has been to enter the antrum from the mouth. The operation that has met with the most favor is that known as Cooper's—through the alveolar process. In case a molar tooth is present it should be extracted and the opening enlarged; or if, as frequently happens, the tooth has been extracted at some previous time, the alveolar process should be perforated at that point. This is best done by means of a small trephine, attached to a surgical engine, or to the electric motor. The instrument should be directed slightly forwards and inwards. This operation has the advantage: 1. that of draining the antrum at its most dependent part, and that the cavity can be readily cleansed by syringing; 2. that it can be performed without the aid of an anæsthetic—a few drops of a 4 per cent. solution of cocaine injected into the gum being sufficient to completely anæsthetize the parts. Its disadvantages are: 1. the liability of food and bacteria from the mouth to enter the sinus and assist in keeping up the suppuration; 2. the occasional necessity of extracting a sound tooth.

If the front wall of the antrum should bulge forward in the canine fossa, then the operation known as Desault's should be performed—resecting a small piece of bone from the fossa. Other surgeons have opened the antrum through this fossa by means of a trocar, and Fergusson recommended an ordinary carpenter's gimlet.

Another operation through the month is that devised by Brandi, who opened the antrum through the hard palate, when a slight bulging of that bone showed a tendency on the part of the abscess to open at that point.

Hartmann, of Berlin, revived, in 1884, a method proposed by Jourdain in the early part of the present century, of washing out and disinfecting the antrum through its natural opening, the ostium maxillare, in the middle meatus. This procedure is also recommended by Stoerk, and they claim to have cured a number of cases in this way. The disadvantages of this procedure are great and the results so uncertain that it will never be

<sup>3</sup> Berl. Klin. Wechschr., Dec. 10, 1888.

generally used; for the antral opening in the middle meatus is situated so far above the floor of that cavity that it cannot be thoroughly drained, and it would be impossible to wash out through a tube of small calibre the thick colloid secretions that are so often found in these abscesses.

The antrum is a pneumatic extension of the nasal chamber and communicates normally with it. When for any reason this communication is shut off the operation that would restore its natural condition would seem the most rational one to select. Jourdain opened this sinus through the infundibulum, in the middle meatus; but this operation never became popular, because, owing to the high situation of the point selected for making the opening, it was difficult to perform it. It is, moreover, not unattended with danger, owing to the possibility of wounding the floor of the orbit.

Mikulicz advises that the antrum be opened through the lateral wall of the nose at a point where it is thin and easily perforated.<sup>4</sup> He uses a special instrument for the purpose, which consists of a sharp, double-cutting knife attached to a handle bent at a blunt angle. It has a flange, so as to prevent its being shoved in too deep. The parts having been thoroughly anesthetized with cocaine, the instrument is passed into the nose, and when about the middle of the inferior meatus, it is turned outward and by firm pressure is made to penetrate the thin wall of the sinus. By a to and fro movement the opening can be made as large as desired.

This operation has the advantage of draining the cavity at its floor, and the opening being easily accessible it can be readily syringed out; the secretions pass through the nose, instead of into the mouth, and there is little danger of the entrance of foreign particles into the antrum to keep up the suppuration. This operation is, however, not practicable: 1. when the nasal chambers are of abnormally small calibre; 2. when there is a deflected septum; and 3. when there is marked hypertrophy of the inferior turbinated body. The principal disadvantage of the operation is that it leaves a ragged edge in the wall of the antrum, against the margins of which the nasal secretions are caught, and becoming dried and hardened may cause an ulceration when an attempt is made to remove them.

The local treatment is very important, the successful issue of the case depending largely upon the solutions used, and the care with which they are applied. The cavity should be irrigated or syringed gently with mild disinfecting and stimulating lotions daily until all suppuration has ceased, when the main opening may then be allowed to close.

The fetor that almost invariably accompanies

these conditions is best overcome by means of a solution of permanganate of potash, after which the cavity should be syringed with a weak solution of common salt and carbolic acid. If the solutions are applied through an opening in the alveolar process, great care should be exercised not to drive them too forcibly against the roof of the cavity, for by so doing distressing pain may be produced in the eye.

This treatment will, in many cases, be all that is required; but in the more obstinate forms of inflammation the local application of the peroxide of hydrogen will be found very efficacious; or, better still, glycozone, a mixture of the peroxide of hydrogen and glycerine. In this preparation we have the combined effect of the glycerine, which abstracts water from the lining membrane of the cavity and keeps it constantly flushed, and the peroxide, which destroys its septic contents and, at the same time, stimulates the inflamed membrane to healthy action. The following are notes of four interesting and instructive cases that have come under my observation:

*Case 1.*—Mrs. E. presented herself for treatment March 3, 1887, giving the following history: She has had frequent attacks of coryza, and for a number of years has suffered from hay fever. Two years ago she had considerable trouble with the second molar tooth in the upper jaw on the left side, which the dentist broke in attempting to remove it, leaving the roots in the gum, and they, from time to time, have caused her pain. About a week prior to consulting me she caught a severe cold at a funeral; since then she has suffered intense pain in the face and in the ear; for several days there has been a watery discharge from the nose. Examination: The left side of the face is very much swollen, and there is some distention of the anterior wall of the superior maxilla; pressure upon the affected side of the face is very painful and gives a crepitating sensation to the fingers; the nose is tightly blocked on the left side, the right side partly open: the first and second bicuspid teeth are absent on the left side, the roots of the second molar remaining and deeply imbedded in the gum; the remaining teeth are in good condition; secretions from the nose are watery in character; examination of the left ear shows a small fistulous opening in external auditory canal just under the annulus tympanicus, about midway of its anterior inferior quadrant, but having no connection with the middle ear; mt. normal in color; hd.  $\frac{2}{4}$ .

On March 4th I perforated the antrum through the canine fossa by means of an ordinary trocar and inserted a Knapps mastoid drainage tube, small size. There was a profuse muco-purulent flow following the operation. The cavity was washed out with a warm solution of common salt and carbolic acid. After the third syringful had

<sup>4</sup> Archiv. für Klin. Chir., Berl., xxiv, 626

been injected the solution passed out of the nose. There was little or no odor present. This treatment was pursued daily for ten days, when the secretions ceased entirely. The drainage tube caused some irritation in the cellular tissue of the cheek, and was removed at the end of the seventh day. Two days after the operation the nose opened on both sides, so that a rhinoscopic examination could be made. The mucous membrane of the left side was deeply congested and very sensitive, the mildest applications causing paroxysms of sneezing. There was also an ulceration of the septum about the size of a silver three-cent piece, laying bare the cartilage. By the use of detergent sprays the inflammatory condition subsided, and the application of a solution of nitrate of silver (gr. v, ad.  $\bar{5}$  j) to the ulcer caused it to heal, completely covering the cartilage.

*Case 2.*—Mr. —, U. S. N., presented himself in the spring of 1888, complaining of a nasopharyngeal catarrh of long standing, and stated that he was sceptical as regards a cure. He complained principally of a profuse secretion of the nose, and when in the reclining position the secretions dropped into his throat, causing him great annoyance.

On examination the inferior turbinals on both sides were markedly hypertrophied, so much so that no satisfactory examination of the upper part of the nasal chambers could be made. The septum was slightly deviated to the left in its upper part. The vault of the pharynx was bathed with a white secretion, but there was no swelling or hypertrophy in this region. The hypertrophied tissue was reduced on both sides by means of the galvano-cautery and chromic acid. The left middle turbinal body was then found enlarged, leaving only a fissure between it and the deflected septum. Pus was found in this fissure and in the middle meatus, reappearing as soon as it was wiped away with absorbent cotton.

Upon further inquiry he stated that in 1867 he had some trouble with the second molar tooth in the upper jaw on the left side. The nerve was killed and the tooth filled without removing the dead pulp. After suffering for two years with frequent small abscesses around the tooth the filling and the decomposed tissue were removed. He dates the nasal discharge from six months after the first filling was put in. He has never had any pain in the face, but it is somewhat fuller on the affected side. The nasal discharge has been constant and very annoying.

Being unable to decide whether there was an abscess of the ethmoid cells, complicating the antral condition, the case was referred to Prof. Harrison Allen, who diagnosed an abscess of the maxillary sinus. At this point my relations to the case terminated, for he was transferred to his

attending physician, Dr. Rixey, U. S. N., through whose courtesy I am allowed to continue the report of the case.

The second molar tooth was extracted and found badly ulcerated at its roots, the opening in the alveolar process was enlarged and the cavity syringed with warm, disinfecting solutions, bringing away a great quantity of very fetid pus and mucus. The treatment has been carefully carried out under Dr. Rixey's direction with marked improvement in his condition. Although there is some secretion still, sufficient to require the cavity to be washed out once a day, he is comparatively comfortable. He wears a gold tube in the alveolar opening, covered by a plate, so as to prevent any of the secretions passing into the mouth.

*Case 3.*—Mrs. P., admitted Sept. 10, 1888, complaining of a fetid discharge into the mouth through an opening left by a recently extracted tooth. She gave the following history: For a number of years she has been afflicted with nasal catarrh, for which she received treatment from numerous physicians without any benefit. About three years ago the secretions from the left side of the nose became so profuse that her life has been a burden. She frequently complained of toothache, and a week ago she had the second molar tooth on the left side extracted. Since then the nasal secretions have greatly diminished, but a great quantity of foul pus is passing constantly into the mouth. She complains of constant nausea and loss of appetite, and is obliged to mop the gums constantly, so as not to swallow the pus. There has never been any swelling of the face, and the patient does not recall having had any tenderness on that side of the face. Present condition: She has an anxious expression; complexion sallow; tongue furred; pus was observed flowing freely from the opening in the gum; a probe passed readily into the antrum; no swelling or pain on pressure on the affected side of face. Examination of the nose shows a collection of thin pus in the middle meatus along the lower border of the middle turbinal on the left side; the right side shows no abnormal condition.

The opening into the antrum was enlarged and the cavity syringed with a solution of permanganate of potash. Immediately there came from the left side of the nose a great quantity of fetid and dark green pus, partly fluid and some of thicker consistency. The odor was almost unbearable. The cavity was washed out daily with a solution of common salt and carbolic acid for nearly three weeks, when the discharge ceased entirely and the opening into the antrum was allowed to close.

*Case 4.*—Capt. —, U. S. A. First seen Feb. 1, 1889. Complained of nasal catarrh, from which he has been suffering for a number of

years. When a cadet at West Point the nerve of the left second molar tooth was killed. Two years later the tooth broke off and a piece of raw cotton was taken out of it in a very fetid condition. He never had any trouble with his nose prior to that time. There has always been more or less pain in the left side of the face since the tooth was filled. About two years ago the secretion of pus from the nose became very annoying, dropping back into the pharynx when he is in the reclining position.

Examination shows the left side of the face to be somewhat fuller than the right. There is a suffusion of the conjunctiva of the left eye which has existed for some time. The second molar tooth in the upper jaw on the affected side is absent; the other teeth are in good condition. There is a thin purulent secretion from the left side of the nose, which is most abundant in the middle meatus; it recurs rapidly after removal. The mucous membrane on the affected side of the nose deeply congested. The alveolar process was opened by means of a small trephine, 3 mm. in diameter, attached to a surgical engine, the gum having been previously anesthetized by the injection of a few drops of a 4 per cent. solution of cocaine. The cavity was readily reached, and it was then syringed out with a warm solution of bicarbonate of soda. A great quantity of fetid pus, mixed with a thick yellow colloid mucus, came out through the nose. There was some bleeding following the operation, but that soon ceased. The antrum was washed out daily for ten days with a solution of common salt and carbonic acid, when the odor ceased, but with little effect on the quantity of secretion of pus. The treatment was then changed to a solution of boracic acid, with no marked improvement following. One application of a solution of bichloride of mercury (1-2500) was made, but owing to the severe pain it caused it was not tried again. I then used a solution of the peroxide of hydrogen with some benefit, but as the improvement was not as rapid as could be desired I was advised to try glycozone. Each application was followed for several hours afterwards by a profuse watery discharge from the nose. The improvement, after the use of this application, was marked from the outset, and in ten days after its first application all suppuration had ceased, the opening in the alveolar process was allowed to close, and the patient was discharged cured.

My experience with glycozone is limited, and I can only judge of its efficacy in this one case; but it seems to me to possess advantages that we have long been in need of in treating these chronic abscesses of the maxillary sinus.

DR. J. O. ROE said: It is my opinion, based on my own experience, that abscess of the antrum is more often caused by diseases in the nose

than by diseases of the teeth. I can now recall eight cases of abscess of the antrum that have come under my care. In four of these cases the abscess was caused by, or associated with, nasal polypi, and there was no disease of the teeth. In three of the other cases the disease was associated with, and apparently caused by, dental caries. In two of the four cases associated with nasal polypi the abscess was not suspected before the polypi were removed, the fetid discharge being attributed to retained secretion that had become decomposed. In every case there was more or less nasal disease. In the study of these cases I concluded that the nasal difficulty had a marked influence in the production of the disease in the antrum; first by the irritation in the nose, causing a turgescence of the living membrane of the interior of the antrum; secondly, by the direct extension of the disease from the nose into the antrum over the continuous surface, and thirdly, by closure of the nasal opening into the antrum by the disease in the nose, thereby causing a retention of the discharge excited by the congestion or disease in the antrum.

DR. LIPPINCOTT was under the impression that purulent disease of the antrum was frequently due to morbid conditions of the teeth. Abscess of the orbit not infrequently has for its *raison d'être* a suppuration process originating in the antrum; and in a large proportion of orbital abscesses arising in this way the primary cause has been dental caries.

DR. E. FLETCHER INGALS, of Chicago, had treated several cases of the kind. One had been cured after about three weeks' treatment, having been washed out repeatedly with peroxide of hydrogen through the normal opening into the nasal cavity. However, he had three cases under observation where every form of treatment had been inefficient in checking the purulent discharge. They had worn tubes in the alveolar process for periods of five, three and two years respectively, and in neither did there appear to be any dead bone, as the discharge was not offensive. He thought that an opening at least 8 mm. in diameter should be made, to allow the introduction of a tube and free discharge.

DR. DALY, of Pittsburg, President, said he had had some experience in the disease of the antrum referred to in the paper just read, and had written a paper upon a series of such cases, which he read before the American Laryngological Association some eight years ago. He was in the habit of opening the antrum through the alveolar process. A surgical engine is not necessary for this. He had once gone into the antrum through the socket of a tooth by means of a small bevel-pointed screw-driver belonging to a gun case. It ought to be borne in mind, however, that the operation is not without danger. One of the brightest men that has ever adorned the Ameri-

can medical profession died a day or two following an operation on his antrum—a man whose teachings have since become regarded as revelations made far in advance of his time and profession. I refer to the late Dr. Beard, of New York. The surgeon who operated on Dr. Beard gave me, shortly after, an account of the operation, which was done with his customary care and skill. The opening was large and made into the antrum by means of the dental engine. Within twenty-four hours after the patient had a chill and other symptoms of septic infection, and died, creating an irreparable loss to the medical profession. The after treatment is necessary to be continued with the utmost care and asepticism for a long time, and not among the least useful and efficient cleanser is one that is nearly always at the hand of the patient, wherever he may be. I refer to soap and water. The third case upon which I operated went to the far West after a few weeks' care, having with him a prescription for an antiseptic fluid which was ordered to be used several times a day. The patient lost the bottle, or broke it, and as a *dernier ressort* used soap and water, found it efficient and continued it until the discharge ceased at the end of six months. He has for eight years remained quite well.

DR. D. BRYSON DELAVAN, of New York, referred to a case of abscess of the antrum which had resisted a great variety of treatments at skillful hands, in which the application of the galvano-cautery to the mucous membrane of the middle turbinated body of the affected side was followed by marked temporary relief.

DR. BRYAN agreed with all that had been said, and further stated that the obstinacy of these cases was, he thought, largely due to incompletely washing out the cavity, leaving septic matter between the partial folds of mucous membrane, which is sufficient to start up the inflammation again after it had apparently subsided.

## LITHOLAPAXY IN CHILDREN.

*Read in the Section of Surgery and Anatomy, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY DUDLEY P. ALLEN, M.D.,

VISITING SURGEON TO LAKESIDE HOSPITAL AND TO CHARITY HOSPITAL; CONSULTING SURGEON TO ST. ALEXIS' HOSPITAL, CLEVELAND, OHIO.

In accepting the invitation of our President to discuss before this body the subject of litholapaxy in children, I have felt no slight degree of hesitation. In the region of country where I reside—Cleveland, Ohio—stone in the bladder is of rare occurrence, so that no one surgeon secures a large number of cases for operation. However, having resided in the Massachusetts General Hospital, and having seen during three years the evolution of the operation of litholapaxy in the hands of

Henry J. Bigelow, and having followed it carefully abroad as performed by Guyon of Paris, Sir Henry Thompson of London, and other surgeons, and having added to this some experience of my own in operating upon children—I shall venture briefly to open this discussion, hoping to elicit from others opinions which will be of value to us all.

Though the operation of litholapaxy on children is a recent one, the success with which it has been performed must, beyond all question, place it among the established operations. Introduced into the Indore Hospital of India by Surg. Major Keegan, it had, according to the latest statistics which are within my reach, been performed by him and his associates in 114 cases, with four deaths. One of these deaths was of a patient with very advanced kidney disease, where operation was earnestly solicited only in the hope of securing relief from suffering. A second death resulted from three attempts to crush a calculus formed about a tilli stalk. Whether or no these two cases be deducted from the number of deaths, as perhaps they might be with fairness, the result is a brilliant one. To be sure, the last report of Surg. Major Freyer gives 165 successful consecutive lateral lithotomies on boys under 16 years of age; but he reports sixteen successful consecutive litholapaxies, and favors the operation in suitable cases. To employ this operation to the exclusion of all others would of course be an error. There are, however, many cases in which it is especially adapted. To point out these cases, and the elements of importance belonging to the operation, is the object of this paper. In doing this we will compare litholapaxy with lateral, median and suprapubic lithotomy.

In comparing litholapaxy to lateral lithotomy it must of course be acknowledged that Freyer's 165 successful consecutive operations upon boys is a more brilliant record than that obtained by any other method. These figures represent, however, the result of vast experience, and are, so far as we know, the best ever obtained. It is not at all impossible that time and experience may yield similar success to litholapaxy.

The removal of large stones from boys by lateral lithotomy is associated with dangers of bruising, hæmorrhage, and possible injury to the reproductive apparatus. Too great size is also a bar to litholapaxy in children, on account of the difficulty in removing the fragments of the crushed stone through the necessarily small evacuating tube. It is in these cases of large calculi that the suprapubic operation has its advantages, as well as in cases of diseased bladder or encysted stones.

In case of small stone, median lithotomy is an excellent operation, and is a formidable rival to litholapaxy in the field to which the latter is especially adapted. In this connection a letter

which I have recently received from Dr. J. G. Kerr, of Canton, China, may be of interest. I take especial pleasure in reading his letter before this body, on account of the admirable work done by this missionary physician in operating on calculi—some account of which was recently published in this country. He writes: "I have not practiced litholapaxy in children. In most of the cases I meet with in boys, the stones are large, and I would be disposed to crush only in cases where the stone was very small. I would prefer the operation I practice, and have performed in many cases, simple incision of the membranous urethra, and extraction of the stone with a small pair of forceps, dilating slightly the opening in the bladder. The operation is simply an incision into the urethra and as devoid of danger as any operation for stone can be. My experience in lithotomy, lithotripsy and litholapaxy amounts to between 700 and 800 operations, etc." I omit the remainder of the letter for lack of time, but surely the opinion of a surgeon of so great experience and recognized ability must weigh strongly in favor of the operation of median lithotomy for small calculi in boys.

Before speaking of the advantages peculiar to litholapaxy as compared with suprapubic lithotomy, I think you will be interested to hear a letter which I have received from Professor Frederick Petersen, of Kiel, Germany, under date of June 3. As you all know, he is the originator of the operation of suprapubic lithotomy as at present performed, an operation which has secured such brilliant results as to entitle him to the admiration of all surgeons and the thanks of humanity. His letter, translated, is as follows: "With litholapaxy in children I have no experience, since I always do the cutting operation, and in difficult cases give the suprapubic operation the preference. When possible after removal of the stone, I unite the bladder with a double line of catgut sutures. The upper portion of the incision in the abdominal wall is united by sutures of silkworm gut. Through the lower portion of the abdominal incision are placed superficial and deep silkworm gut sutures, but these are not tied. This lower portion of the wound is tamponed with iodoform gauze, which remains three days, when it is removed and the sutures are tied—thus fully closing the wound. No catheter is placed in the bladder, but the patient is permitted to pass his water if he is able to do so; otherwise it is drawn off by a catheter as required. *Mit der Litholapaxie kann ich mich noch immer nicht befreunden.*"

Agreeing then, as all must, that there is much in favor of the various cutting operations, and that there are cases suited to each of these methods, let us compare them with litholapaxy. One advantage of litholapaxy over other operations is that it is not a cutting operation. Of course, from the standpoint of good surgery, this should weigh

little in its favor. This much, however, is true: There is no small proportion of cases in which an operation where cutting is required will be long delayed; whereas, should the public understand that calculi can be removed without cutting they will bring to the surgeon at a much earlier period children suffering with stone, and thus render its removal more easy, whatever plan may be adopted. Cutting operations, however, have another and greater disadvantage. Thus far, union of the bladder by first intention after cutting has been rare, by any method save the suprapubic, and in this operation it is not the rule. Though the drainage of the bladder may have its advantages in securing a healthier condition of that viscus, it has the very serious disadvantage of soiling the patient's bed, rendering him very offensive for a longer or shorter period and, when the bladder fails to heal for a considerable time, as is not infrequently the case, resulting in sores that are painful and troublesome. The difference in comfort to the patient, and the time he is confined to the hospital, is also considerable. The average number of days spent in the hospital in Keegan's cases of litholapaxy was 5.7. The average which he gives after lithotomy was 17.61. The average days in hospital of Freyer's cases after litholapaxy was 6.12. We are unable to give a sufficiently large number of cases of suprapubic lithotomy, performed by any one operator on children, to establish any reliable percentage as to time, and it is evidently unfair to this operation to judge it by statistics gathered from various sources. Though a certain percentage of cases heal by first intention, I think it is beyond all question that up to the present time no operation for stone confines patients to their beds for so short a time as litholapaxy. In many cases after litholapaxy in children, the patients are free from all discomfort on the third day, and are up and around. Litholapaxy cannot in any way injure the reproductive apparatus, but very likely the danger of this resulting from lateral lithotomy has been overestimated.

The advantage gained by ability to see the interior of the bladder, as is done in suprapubic lithotomy, is urged in favor of that operation. It is to be remembered, however, that the bladders of boys are, as a rule, in a more healthy condition than those of adults, and that encysted stones are uncommon, so there is rarely any necessity of seeing the interior of the bladder. It has been objected, too, that stones recur more frequently after litholapaxy than after cutting. However, Keegan says that of his 114 cases operated between 1881 and 1886, not a single one has returned so far as he knows, and he adds that had there been a recurrence of the stone it is quite probable that his patients would have returned to him.

A case of my own, bearing on this point, may

not be out of place. A boy was cut for stone in March, 1884, and again in April, 1886. In about one year after the second operation the boy began again to suffer from symptoms of stone, and in February, 1888, I performed litholapaxy. The boy's sufferings had been terrible, vesical tenesmus being frequent, and so severe as to cause his cries to be heard all over the neighborhood. The boy slept very little, and I have rarely seen a patient in a more pitiable condition. Since the performance of litholapaxy the patient's relief has been complete. Should there be any return of the calculus there certainly will not be the hesitation to undergo another operation for crushing that there was in the case of cutting. The success of this case may have been due to the after-treatment. After recovery from the operation I washed out the bladder twice each week during nearly two months with a solution of argenti nitratis, varying from  $\frac{1}{2}$  to 1 gr. to water  $\text{̄}$ iv. This is, I am convinced, a wise plan of treatment, and has resulted in this case much more successfully than did the previous cutting operations. It seems to me as reasonable to treat a bladder with cystitis by washing it out, after litholapaxy, as thus to treat cystitis from any other cause, and I fully believe that by this method all the advantages can be gained that are now claimed for drainage after lithotomy, without the accompanying disagreeable features of bad smells, a filthy bed and irritated skin.

One great difficulty in litholapaxy is the small size of the instruments which must be used. These are larger than would be supposed possible. There are, however, variations in the size of the urethra in different boys. Boys from 7 to 8 years usually admit a 10 to 11, English scale. Some cases occur, however, where even after incising the meatus, the urethra is so small that suitable instruments cannot be inserted. Obviously in these cases lithotomy is the proper operation.

As to whether hard or large stones should be crushed is a question. Certainly there are limitations in both these directions. Though a stone can be measured as to size with some degree of accuracy, still all who have performed litholapaxy have found stones which gave the same measurement by the lithotrite vary greatly in weight and volume. This is easily explicable in consideration of the different diameters by which a stone may be seized. Concerning the density of a stone, it can hardly be possible to form any definite idea of many calculi, until the operation of crushing has begun. It is not rare to seize a stone with a lithotrite, and feel the blades of the lithotrite sink into the stone, and then come upon a hard centre, which is crushed with much greater difficulty. Were one to find a large and very hard stone, it would doubtless be well to abandon litholapaxy, and perform lithotomy—and the size of stone upon which an operator may venture must

be measured somewhat by his experience and dexterity.

Before considering the technique of the operation, we may quote from a letter from Mr. G. Buckston Brown, for many years associated with Sir Henry Thompson, and himself a surgeon of large experience in operations on stone. Under date of May 26, he writes: "I respond with pleasure to your request. I was, I believe, the first publicly to draw attention in our London medical press to the excellent work done by Surg. Maj. Keegan of India, the pioneer of lithotrity in children. I think I cannot do better than enclose you an extract from my article on the choice of operation." . . . "Now, however, that lithotrity at one sitting—by which is meant the crushing and complete evacuation of the calculus at a single operation—is accepted as yielding in the adult far better results than the older or many sittings method, it is not unlikely that the single sitting operation may prove superior even to lithotomy in children, for if efficiently carried out, lithotrity will no longer be open to the objections formerly urged against it. . . . The surgeon may, therefore, choose for himself between lithotomy and lithotrity if called to operate upon a boy; but if inexperienced in lithotrity, he will perhaps do well to decide in favor of the former."

We will now consider the operation itself, and first as to instruments. Their size must vary with the case to be operated upon, ranging from 6 or 7 to 10, English scale, and, as has already been stated, the age of the boy is not a sure indication as to the size of the urethra—since in young children it is sometimes quite capacious. With instruments of so small size the importance of having them of the most reliable manufacture will at once be apparent.

Since it is desirable to use a lithotrite as large as can safely be inserted, it is imperative that its size should not be increased before withdrawal; consequently, provision must be made against impaction. Were impaction of the blades with debris to occur, serious damage might result in their withdrawal. On this account it is found best to construct the lithotrite so that the male blade shuts into the fully fenestrated female blade, rendering impaction impossible. This complete fenestration of the female blade has one disadvantage in my experience, viz.: in crushing a hard stone, pieces which are too large to pass through the small evacuating tube may be repeatedly pushed through the fenestrated female blade without being crushed. When this difficulty has arisen, I have overcome it by inserting a small lithotrite with a flat unfenestrated female blade, having no fear of impaction in crushing the few small pieces which may remain. With a few motions of this lithotrite, I have accomplished what I had failed to do after working with the completely fenestrated blade for a considerable time.

The small size of the evacuating tube shows the necessity of finely crushing the stone, and it is desirable that this be done with as few insertions of the lithotrite as possible. Frequent withdrawal of the lithotrite may cause congestion and swelling of the mucous membrane of the urethra, and consequent difficulty and danger in the insertion of instruments. A recent letter from Guyon of Paris may be of interest as bearing on the question of crushing. He writes: "Calculi are very rare in our country among children, especially those of the better class. My hospital service is one of adults; consequently I have performed lithotripsy only twice on children under 5 years of age. One of these patients had a very small stone; the second had a stone which measured 3 centimeters. Lithotripsy gave an excellent result. I am a strong advocate of lithotripsy among children, but only of lithotripsy at one sitting. Not to empty the bladder completely of fragments, but to leave them, is a gross surgical error. There are but the two methods—either lithotomy or lithotripsy at a single sitting. I find, however, the term litholapaxy a misnomer. It supposes the aspiration of the fragments to be the chief rôle. It is the crushing which is the chief rôle, and lithotripsy is the important thing. I am a strong advocate of aspiration, but this is only a complement, a grand perfecting of the operation to be sure, but it is not the operation, and as a result one does not perform litholapaxy, but lithotripsy. It is thorough crushing which renders possible successful evacuation, and this is especially true with children, since with them one cannot employ large tubes for the evacuation of the fragments." Standing as Guyon does, one of the first surgeons of the world in the line of genito-urinary surgery, his opinions are entitled to much consideration.

As in adults, so in children, the facility with which a stone is crushed depends largely upon its density. I show you here specimens of both hard and soft stones which I have removed from children by litholapaxy, and I have found that a small hard stone requires far more time in crushing than a soft stone of much larger size.

In withdrawing an evacuating tube it is important to bear in mind the possibility of a fragment of stone being caught in the eye of the tube. To draw this through the urethra of a child might cause serious damage—as well as to lose a fragment in the urethra.

The narrow size of the meatus in many cases renders its incision desirable, since less damage is done by its incision than by forcing instruments through it. All manipulations in the child's bladder require the greatest delicacy, and the dexterity and care of the operator will undoubtedly influence greatly the success of his operations.

I show you here two lithotrites, the long one made by Codman & Shurtleff, of Boston, with a Bigelow lock; the short one made by Wies, of

London, with the old lock. Without question the small instrument has its advantages in being lighter, more easily manipulated, and perhaps less likely to do damage by prying upon the neck of the bladder while working. The Bigelow lock is, however, vastly superior to the other, since the same movement with the right hand which locks the instrument begins the crushing and decreases greatly the liability of losing the stone from between the blades.

So far as difficulties of operations in children as compared with adults are concerned—though the operation requires much dexterity and, on account of the size of the instruments, is perhaps more difficult, on the other hand the bladder is less frequently in a seriously diseased condition. There are no enlarged prostates, pockets or projecting bands to give trouble; diseased kidneys are less frequently a complication, and the recuperative power of children is greater than in adults.

To summarize, then, we would say that beyond question the operation of litholapaxy in children is one which must be recognized. It is particularly suited to medium and small-sized stones, and though median and lateral lithotomy are very successful in such cases, we believe litholapaxy will be equally so in skilled hands, and that, beside safety, it has the great advantage of absence of cutting and of the filthy condition of the patient. Suffering is commonly very slight and is confined to a few days, and it is not infrequent for patients to be up and around on the third or fourth day. Patients will not hesitate so long before the crushing as the cutting operation, and should the return of the stone be more frequent after crushing than after cutting—as is by no means shown to be the case—a second operation will be more easily performed than the first, on account of the size of the urethra increasing with the age of the patient. The condition of a boy's bladder is certainly more likely to be favorable to litholapaxy than that of an adult.

Our idea would be that large and hard stones should be removed by the suprapubic operation, especially if for any reason it is desirable to see the interior of the bladder. Medium and small stones are favorable for removal by litholapaxy, unless for some reason the urethra be smaller than normal. The operation of median lithotomy is a favorable one in cases with small stones, but an operator skilled in litholapaxy would do well to choose the latter.

In cases of medium-sized stone, with a urethra not sufficiently large for the introduction of proper instruments for crushing, lateral lithotomy is indicated.

DR. R. P. HARRIS, of Philadelphia, has been elected an honorary member of the American Gynecological Society.

## MEDICAL PROGRESS.

**TREATMENT OF PULMONARY PHTHISIS.**—At a special meeting of the Allegheny County Medical Society, held August 20, 1889, DR. LANGE reported a new method for the treatment of pulmonary phthisis. We quote from him as follows: The method consists of the inhalation of vaporized mercury and iodine. Of the results of this method I have nothing to say. I cannot forget that grass has not yet grown upon the grave of gaseous enemata, and I am aware that many men, many years and many cases are required to produce evidence of the usefulness of any remedy or method in the treatment of anything, even when the remedy or method possesses usefulness. I report this method because I desire co-workers.

It suggested itself to me that vaporized mercury, if brought into more or less direct contact with the bacillus of Koch, might destroy this, and that iodine, if applied directly to the ulcerating surfaces of lung tissue might effect a more powerful beneficial action than that resulting from its ordinary method of administration. I have had, and still have, the valuable assistance of Dr. Tingley in the preparation of apparatus and in devising ways and means by which these vapors may be satisfactorily administered to patients. This has presented many difficulties. A principal one is, that I know of no manner as yet by which a definite, a known quantity can be given. The vaporized mercury salts are resublimed and deposited upon the cooler parts of the apparatus. This is particularly true of the inhaling tube, which is always the coolest part of the apparatus. The consequence of this is that patients receive always an unmeasured, an accidental quantity of these salts or vapors, and not a quantity which is measured or known. To this fact are due two accidents, namely, that one very feeble patient was violently purged, and another was salivated. However, we hope to overcome this defect of apparatus and to be able soon to give patients exact quantities of these salts. The desideratum is an inhaling tube which will bear the temperature necessary to hold the mercury salts vaporized up to the lips of the patient, and which at the same time shall be flexible. Flexibility is almost a necessity; a feeble patient cannot breathe deeply and persistently from a stiff tube, a glass tube such as I now use.

I have found that the only salts of mercury available for this purpose are the red oxide and calomel. All others are reduced before being volatilized. I began with the iodide of mercury. This and all others when used result in the vapor of metallic mercury only. I have found no objection, however, to the use of metallic mercury, only it is to be noted that when other salts than calomel and the red oxide are used, the patient receives the vapor of metallic mercury.

Can the vapor of mercury, or anything inhaled, reach the bacilli in a tuberculous lung? Those bacilli, which are in consolidations, provided such consolidation is connected with a pervious bronchial tube, those in lung cavities furnished in the same manner, those in the bronchial tubes, those in the alveoli, and those in the sputum may be reached by this vapor, or by anything which may be deeply and persistently inhaled. But these bacilli are comparatively inert; they are harmless; they have already accomplished their mission of destruction, and are being extruded from the body. Those whose destruction is very much more desirable, those which have not yet, but which certainly will, produce consolidation and softening, *i. e.*, destruction of lung tissue, those in the pulmonary connective tissue, and the lymphatic sheaths of the blood vessels, can these be reached by anything that may be inhaled? Again, if we grant that in a certain patient every bacillus has been destroyed, this is by no means synonymous with his cure. Evidences of this fact are presented daily; patients die of non-tuberculous phthisis very readily. And the tuberculous patient with every bacilli in his lungs destroyed, possesses still that fatal predisposition, and will be reinfected.

It is a question also whether mercurial vapor is a germicide. No one will deny this property to corrosive sublimate. But corrosive sublimate is not volatilizable, and volatilized mercury, volatilized calomel, and red oxide, are very different substances indeed.

Despite these theoretical objections I am encouraged to proceed with this treatment of phthisis, and when I have perfected the apparatus and have a series of cases certainly tubercular, as demonstrated by the discovery in the sputum of the bacilli, which Dr. Matson has kindly consented to do for me, I shall report again to the Society.

**THE DIURETIC ACTION OF CAFFEIN IN COMBINATION WITH PARALDEHYDE.**—Their attention having been drawn to the excellent experimental studies made by VON SCHRODER concerning the diuretic action of caffein, V. CERVELLO and G. CARUSO-PECORARO (*Sicilia Med.*) have tested its effects in the human subject. The first patient, a woman, 40 years of age, exhibited a moderate degree of intra-peritoneal exudate, the result of venous stasis from a heart lesion. A combination of caffein with paraldehyde resulted on the first day in an increase in the excretion of urine from 900 ccm. (the previous amount) to 1,690 ccm. By the eleventh day the amount had been increased to 2,100 ccm., and the ascites had markedly diminished. In like manner a similar result was effected in the case of an individual 22 years old, who also suffered from a heart lesion. In a case of chronic diffuse nephritis with marked edema,

the patient's condition was considerably improved by the administration of caffeine and paraldehyde the quantity of urine passed increasing from 800 ccm. to 2025 ccm. Quite as favorable as this was the result produced in a second and similar case of nephritis. This combination of remedies has also produced absorption in sero-fibrinous pleuritis, with abundant exudate and no tendency to spontaneous resorption.

The paraldehyde is given either in capsules or solution in doses of 2-3 grm. two or three times a day; the caffeine in doses of 0.25-0.5 grm. The paraldehyde should always be administered toward evening in order that its soporific effects may be felt at bedtime. In ascites following cirrhosis of the liver, the usual and favorable diuretic effect of the caffeine was not obtained.—*Centralblatt f. Klin. Med.*, No. 34, 1889.

REPORT OF TEN OPERATION UPON THE KIDNEYS.—(E. DOVEN, before the Académie de Médecine.) These ten operations were performed by the lumbar method. Three patients upon whom nephrectomy was performed died. In two of these there was old renal tuberculosis, and the opposite kidney had undergone amyloid degeneration. The third had suffered from attacks of hectic fever for six months and the kidney contained a large calculus. In all three cases the operation presented great difficulties on account of the size of the purulent kidney, as well as the extent and firmness of the adhesions. The removal of the kidney in the other cases operated on was relatively easy and recovery occurred without the slightest complication. One of these had undergone an operation for the establishment of an uretero-cutaneous fistula forty-two days before the nephrectomy, the left ureter having been divided during an ovariectomy.

Two other cases are of particular interest. One was that of a woman 42 years old, who submitted in June, 1887, to removal of a tuberculous kidney together with the upper third of the degenerated ureter; to-day she is in perfect health. In another case, two years after removal of the right kidney (which was reduced to a fibrous shell containing more than 100 calculi) it became necessary to perform nephrotomy and lithotomy on the left side on account of a calculus deeply engaged in the ureter. This intervention was followed by complete success.

In two operations nephrorrhaphy was performed through a simple vertical incision. The kidney was fixed to the quadratus lumborum and the musculo-en-aponeurosis by four sutures, which were pressed as deeply as the pyramidal region; the fatty capsule was resected; the results have been excellent.

In cases of lithiasis nephrotomy is indicated, being preferable to nephrectomy, because a very small bit of renal tissue becomes precious when

the second kidney is affected. Incision followed by ennetting of the cheesy foci should be preferred to nephrotomy in cases where there is a very large and very adherent tubercular kidney. *Le Bulletin Médical*.

CAUSE OF LOCAL RECURRENCE AFTER AMPUTATION OF BREAST FOR CARCINOMA.—(LOTHAR HEIDENHEIN in Langenbeck's *Archiv für Klinische Chirurgie*, vol. 39, Heft 1.) In making a most thorough and complete study of several thousand microscopic sections taken from the cut surface of eighteen different breasts, removed by Prof. Kuster, he has come to the following conclusions: That although in each case the cut surface was a considerable distance from the tumor, in nine cases portions of the fascia of the pectoralis major, which remained, certainly contained microscopic collections of carcinomatous cells, in three others this condition was possible although not proven, while six cases seemed to be free from remnants. The clinical observations of these cases so far corresponds very closely to this. He found that the invasion of the surrounding tissue took place through the lymph channels and along the lymph spaces surrounding blood vessels and in the connective tissue trabeculae, but reaching the fascia of the pectoralis major they filled this structure, but did not penetrate the muscle except in advanced cases, *but this fascia can be removed only by taking with it a layer of the muscle*. This is the practical point which will probably save hundreds of cases from having recurrence of mammary cancer in the future. The article covers 70 pages and is of very great scientific and practical value. The author also confirms other previously observed facts.

AN ABORTED OVUM OF THREE MONTHS' DEVELOPMENT.—In the Obstetrical Society of Vienna, PROF. GUSTAV BRAUN exhibited an aborted ovum of three months' development, in which the relation of amniotic bands to arrested foetal development was susceptible of beautiful demonstration. The foetus itself was macerated; the cord 9½ cm. long, which was torn during birth, passed from the umbilical ring under the left axilla to the neck, around which it took a turn and then passed around the right shoulder, which appeared as though ligated by it. There were also fibrous bands in connection with the fingers and toes. Prof. Braun thought that the relative shortness of the cord was the cause of death, and that if development had advanced spontaneous amputation would probably have occurred.—*Cent. für Gyn.*, 1889, No. 34.

YELLOW FEVER is epidemic in many localities in Cuba, the mortality being relatively high, especially in Havana.

SATURDAY, OCTOBER 5, 1889.

THE CAUSES OF WASTE IN CONSUMPTION.

Loss of tissue is so characteristic of pulmonary tuberculosis that it has given the popular name to the disease. Not the fat alone of the body is thus affected, but it is also observed in the muscles and organs. This loss of weight is so early a symptom that there would seem to be an inherent tendency in the disease in this direction. Still, a little consideration shows there are certain conditions capable of causing waste independently of any inherent influence in this direction. In most cases even of incipient phthisis there is a positive want of sufficient nourishment to supply the needs of the organism. This is due generally to a loss of appetite amounting to actual aversion for food, as well as to defective assimilation. In some, however, the appetite remains good, but either the digestion is imperfect or the system is incapable of appropriating the nourishment supplied. There is, therefore, in these patients profound anæmia. Yet, the fact that many times anæmic individuals, who are not consumptive, take on fat, apparently as the result of incomplete oxidation, would seem to indicate that the anæmia of phthisis is linked to some subtler cause of wasting, some molecular defect of the tissues, some chemico-physiological peculiarity.

Later on in the development of this malady there are certain very apparent causes of the emaciation, chief among which is fever. That fever causes an increased destruction of the tissues is proved by the augmented excretion of carbonic acid, according to Landois, of from 70 to 80 per cent., and by the increase in the amount of urea,

uric acid, and other solid constituents of the urine. The urea is increased from one-third to two-thirds and the potash may even reach many times its normal amount. But not only does fever directly influence the consumption of tissue, it also still further impairs appetite and digestion, in this way favoring waste. An indirect proof of the deleterious effect of an elevated temperature, and an indication for treatment, is afforded by the fact that when the body temperature becomes permanently reduced to the normal, the weight of the patient is apt to increase or at least remain stationary.

Another potent factor in promoting emaciation is profuse sweating. This symptom is complained of because productive of so much discomfort and exhaustion. It is serious, however, for another reason, viz.: because it robs the system of much valuable material. More than 1 per cent. of the perspiration is made up of solids, organic and inorganic, and when it is considered that 2 lbs. of liquid leave the body in twenty-four hours in the form of insensible perspiration, it becomes intelligible how serious must be the loss from the night sweats of the consumptive. To be sure, the great loss of fluids thus sustained can be rapidly recovered from by the ingestion of more fluids, but the salts contained in the perspiration are sadly missed by the system, and, if not replaced, form a positive source of waste.

In most cases, particularly those at an advanced stage, the profuse expectoration is an additional cause of emaciation as well as of loss of strength. Even when there is no blood in the sputa, the system is subjected to a heavy tax to contribute the leucocytes, mucus and other elements composing so large a part of the expectoration. When, moreover, hæmoptysis occurs, very decided impetus is given to the wasting process, and the patient appears to fall away before one's very eyes. Such also is the case if there supervenes suddenly one of those obstinate diarrhœas that torment the consumptive. A patient, who may have regained a comparatively normal daily temperature and seems to be actually taking on a little flesh, will upon such an exhausting discharge grow suddenly gaunt and haggard and progressively fail despite all measures to the contrary.

In conclusion it may be said, the conditions that influence waste are the very phenomena which stamp this disease with its peculiar char-

acter. There can be no consumption without waste any more than there can be fever without elevation of bodily temperature, and in some this loss of tissue is so out of proportion to symptoms explaining it, that there would seem to be some subtle cause existing in the very nature of the disease which defies analysis.

#### LAWSON TAIT ON FIBROIDS OF THE UTERUS.

A few weeks ago we called attention to the views of THOMAS KEITH on Apostoli's treatment of uterine fibroids by electricity. It is, perhaps, no more than fair to give place to the rejoinder of the most prominent advocate of the purely surgical method of dealing with this condition. In a lecture, published in the *British Medical Journal* of August 10, 1889, MR. TAIT calls attention to the fact that hysterectomy, which Mr. Keith seems to consider the only alternative treatment, is only required in a small proportion of cases, and that the great majority can be satisfactorily treated by the comparatively safe and simple operation of bringing about the menopause by extirpation of the uterine appendages. He claims that "the complete and permanent efficacy of this method of treatment has been established by evidence beyond all cavil; in fact it stands unrivalled in the history of modern surgery," and states that his mortality in 262 consecutive cases has been only 1.23 per cent. To the operation of hysterectomy he expresses as strong a repugnance as Keith; but, although he does not expressly discuss this point, he evidently has little faith in the efficacy of electricity in cases which call for the severer measure.

To electricity he objects that it is tedious, and, notwithstanding Keith's statements to the contrary, may be very painful, citing a case, treated in Paris, in which electricity was used thirty-three times during a period of three months, and thirty-one times the patient was under anæsthesia. That it sometimes fails when administered by thoroughly competent persons, he has had evidence in cases which have come into his own hands, and there is danger of losing precious time in unsuccessful treatment.

He complains that Keith furnishes many statements, but few facts, and wishes for precise information in regard to the mortality of the electrical treatment, the permanency of the results

secured, and the comparative convenience and expense of the two methods.

He concludes by quoting what he calls the "prodigious statement" of Keith, that in 10 per cent. of his cases of hysterectomy the operation was followed by insanity. On this point he says: "In not one of my hysterectomies has insanity followed the operation. I have seen insanity follow removal of the appendages for myoma in two cases, but in one the patient was insane from the moment she came out of the chloroform, and she was "queer" before she went under it."

In view of such results as Tait has achieved it is not surprising that he should have little inclination to change the methods which have proved so successful in his hands. If any value is to be allowed to evidence, however, it can hardly be doubted that very satisfactory results have been attained by the electrical treatment. Martin, of this city, at the meeting of the Illinois State Medical Society, May 22, 1889, reported one hundred consecutive cases treated by Apostoli's method, without a death, with complete cure in eight cases, symptomatic cure in sixty-eight others, and decided improvement in the symptoms of most of the remainder. If such results can be secured by this method and should prove permanent, it is likely that many women will prefer, even at the cost of some pain and inconvenience, to avoid a mutilation which is repugnant to their feelings and, besides the inevitable result of sterility, is not always exempt from other unpleasant consequences. Glævecke, of Kiel, found that a depressed, low-spirited condition was generally observed after removal of the ovaries; in three cases out of forty-three insanity followed the operation, proving permanent in one. Sexual desire and pleasure were diminished in nearly all the patients, and the disturbances usual at the menopause were prolonged, in a number of cases, for four or five years.

Brilliant as have been the results of surgery in the relief of this affection, it can hardly be said that they leave nothing to be desired, and anything which promises the benefits without the drawbacks of the operation with which Mr. Tait's name is specially associated is worthy of careful trial. It is hardly probable that electricity will wholly supplant operative treatment, but it may well be that when both have been thoroughly tested it will appear that each has its appropriate field of usefulness.

## EDITORIAL NOTES.

## HOME.

**THE AMERICAN PUBLIC HEALTH ASSOCIATION.**—The seventeenth annual meeting of this Association will convene at Brooklyn, on October 22, 23, 24 and 25. From a review of the topics to be presented at that meeting, a list of which will be found on page 504 of the present issue, and from the prominence of those who are to engage in the discussion of these subjects presented, we have reason to believe that the meeting will be one of unusual interest. We shall endeavor to present our readers with as full a report of its proceedings as the columns of *THE JOURNAL* will permit.

**THE MEDICAL COLLEGES** in Chicago opened last week with a large attendance of students.

**PROPOSED PUBLIC BATHS FOR CHICAGO.**—The Trade and Labor Assembly some months ago petitioned the city council for a system of public bath houses. The matter was referred for investigation, and Chief Tenement Inspector Young has prepared plans. He favors bath houses built on the cottage style, 100x55 feet, each to contain forty-one dressing rooms and an office for the keeper. The cost will be about \$3,000 each. The water at one end will be four feet deep and five at the other end. The slope to be gradual. Mr. Young thinks that one should be anchored in each of the park lakes in the city, and others along the lake shore. The report will be sent to Commissioner Purdy and by him referred to the council.

**THE AMERICAN ACADEMY OF MEDICINE**, of which Dr. Leartus Connor, of Detroit, is president, and Dr. R. J. Dunglison, of Philadelphia, secretary, will hold its annual meeting in Chicago, on the 13th and 14th of November.

**WORK OF THE GEOLOGICAL SURVEY.**—Major J. W. Powell, chief of the geological survey, was in Chicago last week, after fifty-five days' work as advisory member of the senatorial committee investigating irrigation in the West. The committee began work at St. Paul and concluded its labors at Ogallala, Neb. It visited the Dakotas, Oregon, Montana, Washington Territory, Idaho, Utah, Nevada, California, Arizona, New Mexico, Texas, Indian Territory, Kansas, Colorado, Wyoming, and Nebraska—every State containing arid lands.

Eighty meetings were held and 200 witnesses heard. Major Powell thinks over 100,000,000 acres of land can be irrigated successfully. The resolution under which the committee was appointed did not contemplate appropriations for building reservoirs and artificial lakes—merely a thorough survey of the territory, that the work may be done by private enterprise. Major Powell thought Congress would never take charge of the construction of the ditches and reservoirs. The survey of Illinois, particularly along the proposed line of the drainage canal, is progressing, and will probably be completed in another year.

**PRIZE OF THE PHYSIOLOGICAL SOCIETY.**—Dr. Wier Mitchell has placed at the disposal of the American Physiological Society the sum of \$200 as a prize for original work in nerve physiology, which work shall have been done after January 1, 1886, and before October 1, 1890. At the latter date the competition closes, and essays must be in the hands of Dr. H. Newell Martin, secretary of the Society. The award will be made by the council of the Society. The subject, which has been selected by Dr. Mitchell, relates to the rate of nerve transmission in man, and the circumstances which cause that rate to vary.

**MEDICAL SOCIETY OF VIRGINIA.**—At the twentieth annual meeting of this society, held in Roanoke, September 3, 4 and 5, 1889, the following officers were elected for the ensuing year: Dr. Oscar Wiley, of Salem, president; Dr. J. M. Estill, of Tazewell Court House; Dr. Alfred C. Palmer, of Norfolk, and Dr. Casper C. Henckel, of New Market, vice-presidents; Dr. Landon B. Edwards, of Richmond, recording secretary; Dr. J. F. Winn, of Richmond, corresponding secretary; and Dr. Richard T. Styll, of Hollins, treasurer. Dr. John S. Apperson, of Glade Spring, was chosen to deliver the address to the public and profession during the session of 1890. Dr. C. T. Lewis, of Clifton Forge, was selected as the leader of the discussion of the selected subject for 1890—"The Treatment of the Summer Diarrhœa of Children." Dr. R. F. Young, of Love's Mill, and Dr. P. B. Green, of Wytheville, were nominated for commission as members of the Medical Examining Board of Virginia, to fill vacancies occasioned by two resignations. Rockbridge Alum Springs was selected as the place for the annual session of 1890, some time between the 25th of

August and the 5th of September, as the Executive Committee might hereafter determine.

**JELLY-FISH STING.**—*The Medical News* says that bathers who have encountered the long tentacles of a medusa will be pleased to know that the "sting," or erythema, may be speedily relieved by the application of water rendered alkaline by common washing soda, in the proportion of an ounce of soda to about two quarts of water. Dr. B. M. Richardson states in the *Asclepiad* for September, that he has personally tested the efficacy of the treatment, and has also used it successfully in several severe cases.

**THE NATURAL MINERAL SPRINGS OF THE UNITED STATES.**—An important meeting of gentlemen interested in the natural mineral springs of the United States, was held at Washington last week, and a temporary organization effected by electing Thomas Tomlinson president and Dr. A. Emfield secretary and treasurer. The attendance was large, and a general convention was called to meet at Chicago, November 19. A committee was appointed consisting of James W. Inches, D. L. Sterling, and Alfred Moore to formulate a plan of permanent organization, and to report at the Chicago meeting.

**HOW MUCH SHOULD A CITY PAY ITS HEALTH OFFICER?**—The Michigan State Board of Health has recently published a paper by its Secretary, Dr. H. B. Baker, in which he asks the question how much the average city or village can afford to pay its Health Officer. He answers this question in this way: Statistics which can not be questioned prove that in those localities in Michigan where the recommendations of the State Board of Health are carried out about 80 per cent. of the deaths from diphtheria and scarlet fever are prevented by the thorough isolation of all infected persons and the thorough disinfection of all infected persons, things and places. Statisticians usually value a person in the prime of life as worth to the community about \$1,000. Dr. Baker thinks that in a village of 1,500 inhabitants a health officer can easily save the lives of two children and one grown person in each year, and he concludes that such a village can well afford to pay its health officer \$2,000 for the prevention and restriction of scarlet fever, diphtheria and typhoid fever, and make money by the transaction.

#### FOREIGN.

**YELLOW FEVER IN SPAIN.**—Reports have been going the rounds of the papers relative to an alleged epidemic of yellow fever at Vigo. There were several cases of gastric and typhus fever, but none of yellow fever.

**LEPROSY IN THE ORIENT.**—In the Academy of Medicine, Paris, M. Zambaco recently stated that the question of the contagionness of leprosy, though admitted by many, was not yet settled in his own mind. He had not discovered an example of contagion either in Turkey or in the other oriental countries that he had visited. Until he is better informed he will remain an anti-contagionist, for he believes that if leprosy is contagious at all it is only very exceptionally so.

**CHOLERA** is prevalent at Pekin, China, and nearly all the foreign residents have fled to the mountains.

**OVERCROWDING OF THE PROFESSIONS IN GERMANY.**—Prof. Lexis of Berlin has been writing a pamphlet on the undue increase in all the learned professions. He says there are twice as many students as can hope to make a living by the professions which they are preparing to enter.

**THE French law** gives a physician's claim against the estate of a deceased patient precedence.

**ANOTHER ELIXIR OF YOUTH.**—The *British Medical Journal* says that it is stated by a Pesth newspaper that Dr. Szikszay, a Hungarian physician, has been making experiments in the State Prison at Engelsfeld by injecting a liquid, the composition of which is not revealed, into aged persons. The results are said to be remarkable. The strength of the "subjects" was tested with a dynamometer before and after the injections. In the case of a man aged 75 years the strength was found to be increased after the seventh injection from 14 to 19 kilograms, and after the thirteenth to 35 kilograms. Experiments on men and women of different ages showed, as might be expected, marked individual differences. We may take the liberty of suggesting to Dr. Szikszay that he should communicate the details of his experiments to the Imperial and Royal Society of Physicians of Vienna, and then publish them in full in some medical journal. The after results, if any, should also be made known.

## TOPICS OF THE WEEK.

## STUDY OF YELLOW FEVER.

DR. GEORGE M. STERNBERG, Major and Surgeon, United States Army, has just returned from a six months' stay in Cuba, where he has been continuing his researches with reference to the cause and prevention of yellow fever.

He found in the hospitals a sufficient number of cases, and in the course of the summer made thirty autopsies. He has brought with him specimens in alcohol and cultures of microbes with which he will continue his investigations during the winter at the Johns Hopkins University. At the end of this time he hopes to present a general report of his investigations to President Harrison.

"My researches up to the present," said Dr. Sternberg, "have not led to a positive demonstration of the specific cause of the disease. But I have isolated a considerable number of pathogenic bacilli—disease-producing germs—from the intestines of yellow fever cases, and have strong hopes that one or more of these may prove to be the specific germ. I have confirmed my previous conclusions as to the absence of specific microbe organism in the blood and tissues of the patient, and have failed to find in any of my cases the germ which Dr. Freire of Brazil has claimed to be the cause of the disease. For this reason I have given my attention entirely to the bacilli of the alimentary canal. As none of the lower animals are subject to yellow fever, and inoculation will therefore be impossible, it will be extremely difficult to arrive at a positive demonstration. It will, moreover, be necessary to make extensive comparative researches to ascertain the character of the bacterial flora in the intestines in other diseases. I have isolated a long list of unknown and undescribed bacteria found in the digestive system of yellow fever patients. But I have yet to prove that some of these are uniformly constant in this disease and are not found in others. For instance, in all my researches I have never found the comma bacillus of Koch, now generally believed to be the cause of cholera."

## PHENACETIN.

In a paper prepared by DR. B. FRANK HUMPHREYS, of Texas, upon "The Uses and Abuses of the New Antipyretics," he quotes the clinical experiences of various observers in connection with the uses of this new remedy, as follows:

Dr. G. Kobler, assistant at the medical clinic of Prof. von Bamberger, at Vienna, under whose direction he experimented, was the first to observe the effects of phenacetin as an antipyretic remedy. Fifty cases with high temperature came under his observation. Dr. Kobler makes the following remarks with reference to the properties of this new antipyretic:

(a) A specific influence on the course of the disease itself was never observed.

(b) Phenacetin in every case was borne well without any toxic or even disagreeable effects.

(c) The reduction of temperature is, as a rule, pretty

rapid, while the subsequent rise is comparatively much slower. Large single doses of phenacetin have a decidedly more energetic effect than small doses frequently repeated.

(d) There was never any cyanosis or collapse, such as is not infrequently seen during the administration of some other antipyretics. Even in the ten cases of pneumonia treated with phenacetin there was no deleterious action on the heart, which we often meet with in the course of this disease.

Summarizing his experience, Dr. Kobler comes to the following conclusions:

1. Phenacetin is a very efficacious antipyretic.
2. It has no disagreeable or deleterious effects, such as cyanosis or collapse.
3. It produces decided euphoria.
4. It is best administered in single doses of from 8 to 12 grs., instead of smaller ones given every hour or two.
5. The reduction of temperature after such a dose is from  $3.6^{\circ}$  to  $4.5^{\circ}$  F.

Dr. Hugo Hoppe, of Berlin, under the direction of Prof. Albert Fraenkel and Dr. Paul Guttman, medical director of the City Hospital at Moabit, has collected notes of twenty cases affected with maladies in which there was pyrexia, nine of whom had typhoid fever. Dr. Hoppe's paper is a carefully written thesis, very elaborate and minute in clinical notes, taken with reference to the therapeutic action of phenacetin. He arrives at very similar conclusions to his predecessor, Dr. Kobler; and although neither of these clinicians observed any untoward effects of the drug, even in doses of from 15 to 30 grs., Dr. Paul Guttman afterwards informed Dr. Hoppe that he had observed a severe chill in a child during the subsequent rise of temperature after the exhibition of phenacetin, without stating, however, the quantity administered or age of patient. Now, it is alleged that in Kobler's fifty and Hoppe's twenty cases there were no rigors observed upon the subsequent rise of temperature. A reasonable inference, therefore, would be that in Dr. Guttman's single case the child had probably received a dose which "transcended the exclamation point," or that it may have been a single exception to the action of the medicine as a rule.

Professor Giuseppe Cattani, physician to the Grand Hospital at Milan, has tried phenacetin in more than fifty different cases, mostly febrile diseases, and his reports are almost exclusively favorable. One of the many forms of disease in which he has used phenacetin with advantage is rheumatic endocarditis, in which, he says, it acts like a tonic by rendering the heart's action steady, even where a valvular lesion has been established, as, for instance, in mitral incompetency. Prof. Cattani, like Prof. Dujardin Beaumetz, thinks that in its analgesic property, phenacetin outrivals its predecessors. Dr. Gaiffé has found phenacetin of considerable benefit in nervous polyuria. He says the heart and pulse are never influenced by this drug. Drs. Cesari and Burani confirm most of the antecedent observations of others with reference to the action of phenacetin. Drs. Misrachi and Rifat contribute a clinical study of phenacetin, in which they also recommend the drug as an effective

antihyperthermic and antinervine remedy. In children's practice they advise it to be rubbed up in some sugar, which, they say, totally disguises any taste or smell.

Prof. Rumpf, of Bonn, says that this drug, as now produced by the manufacturers, is almost chemically pure phenacetin, and that it has no disagreeable action whatever, if given in doses not exceeding 45 grains daily. In doses of 15 grains daily, he says, it is absolutely harmless, and that there are no nausea and vomiting, no cyanosis and syncope, and no untoward symptoms in patients with high temperature.

The dose administered by Prof. Rumpf was 15 grains, by which the temperature was reduced  $3.6^{\circ}$  to  $5.4^{\circ}$  F. within from two to four hours. In a case of pleurisy, for instance, the temperature fell from  $104^{\circ}$  to  $99.2^{\circ}$  F., and on the next day from  $103^{\circ}$  to  $99^{\circ}$  F. within four hours. Having found that 15 grains of phenacetin would in some cases cause the temperature to fall below the normal, Prof. Rumpf advises that the dose given in febrile maladies should never be larger than 8 grains; but, strange as it may seem, even when given in doses of 45 grains, it is alleged that the drug never caused any nausea, vomiting, chilliness, cyanosis, or eruption of the skin; only profuse perspiration was observed in some cases.

Encouraged by the favorable results obtained by Hoppe, Heusner, and Dujardin-Beaumetz, with the administration in cases of hemicrania and other forms of neuralgia, Prof. Rumpf tried the drug, with regard to its analgesic property in a great number of cases, with uniformly satisfactory results, the dose in such cases being 15 grains. The effects of the medicament were observed in many cases within thirty or forty minutes after its administration, in other cases not until an hour or two had elapsed.

From a considerable clinical experience with this new candidate for favor, Prof. Rumpf arrives at the following conclusions with regard to its therapeutic properties:

1. Phenacetin is an antipyretic of reliable action and certain effects, from all untoward and disagreeable symptoms.

2. Phenacetin is to be recommended as an antineuralgic in 15-grain doses, viz.:

- (a) In all cases of vaso-motor neuroses.
- (b) In locomotor ataxia against the lancinating pains, and in cases of chronic neuritis against neuralgia.
- (c) In various cases of neuralgia, to soothe the pain at least.

Prof. Mueller, at the meeting of the Verein für Innere Medizin, at Berlin, July 2, 1888, in a discussion with regard to the merits of phenacetin, confirmed the observations of the authors detailed herein, and further added that in daily doses of 75 grains or less its exhibition is never followed by cyanosis and methæmoglobinuria. This statement if found true by other observers, will prove to be a strong argument in favor of the claim that the drug is comparatively safe in large doses, and innocuous in medicinal doses.

Some distinguished English physicians have expressed a favorable opinion of phenacetin, corroborating the observations of the writers already mentioned.

Prof. Dujardin-Beaumetz says: "Phenacetin is a rival of antipyrin and antifebrin; in a word, it is an antipyretic and a nervous sedative. It is not unlikely that it is more active than either of the two agents just named. . . .

"I have tried it in doses of 5 grains, given in wafers, and I must say that I have observed—as others have done before—a considerable reduction of temperature in tuberculous, feverish patients, and in those suffering from typhoid fever. This reduction, which amounted to  $5.4^{\circ}$  F. in some cases, is remarkably persistent, although the dose is comparatively small; it lasts from eight to ten hours. On the duration of the disease itself the new remedy has no influence, just as with the other antipyretics.

"Phenacetin is also a strong analgesic, more powerful in its action, perhaps, than either antipyrin or antifibrin. And it acts very rapidly, in spite of its insolubility; in the gastric juice, about twenty minutes after its administration, its effects may already be observed.

"I will state in addition that phenacetin does not produce cyanosis, like antifibrin, and that in contradistinction to the latter, its presence in the urine may be detected; ferric perchloride will turn red, and cupric sulphate will turn green, if added to urine containing phenacetin."

Prof. R. Lépine, of Lyons, in a paper on typhoid fever, also expresses satisfaction with the effects of this new medicament. He says, however, that after daily doses of 90 grains there is some headache and some cyanosis; but in doses of 45 grains he says it does not affect the heart, and produces neither cyanosis nor any other untoward symptom, except, perhaps, some sweating. He gives it in 8-grain wafers, of these six to eight a day. From the foregoing it is to be inferred that the drug, in very large doses, or perhaps if long-continued in smaller doses, may produce blood changes not very unlike the effects of antifebrin.—*Therapeutic Gazette*.—*The Practitioner*.

#### HEMORRHAGE FROM THE LARYNX.

In a paper read by DR. WILLIAM PORTER, of St. Louis, at the eleventh annual meeting of the American Laryngological Association upon this subject, he presents the following conclusions:

1. Laryngeal hæmorrhage may occur from simple local conditions.

2. Unless associated with other and more positive symptoms, it is not indicative of pulmonary lesion.

3. It is possible, through the passing of blood from the larynx into the lungs, that pulmonary disease may be incited.

4. Care should be taken to distinguish between pulmonary and laryngeal hæmorrhages, not only for the sake of more exact treatment, but especially because of the more favorable prognosis that may be given in many cases of the latter condition.—*New York Medical Journal*.

A NEW hospital has been erected in Denver, Colo., at a cost of \$30,000.

## PRACTICAL NOTES.

### MILK SUGAR AS A DIURETIC.

PROF. SÉE has recently presented the result of his study of the diuretic action of milk sugar, which he considers the most reliable of all diuretics. In diseases of the heart and stomach, and also in renal or cardiac affections accompanied by dropsy, its diuretic qualities render it very serviceable. Milk in these cases, as is well known, is of great value, not only on account of its diuretic properties, but also because it is so complete a food. Three or four quarts of milk a day may be used with advantage, but the proportion of sugar in milk is rather too small. Prof. Sée has discovered, by experimenting successively with the different constituents of milk, that lactose is the active agent. The action of the other constituents of the milk, such as the water and the salts, is inconsiderable, the chloride of sodium adds nothing, and the salts of potassium very little, to the polyuria induced by the sugar of milk.

This sugar is found in all kinds of milk, is crystalline, and quite soluble in water. About three ounces of it dissolved in two quarts of water, with complete suppression of every other liquid, as soup, tea, wine, mineral water, etc., will afford marked diuresis in all cardiac troubles, no matter what the lesion may be, though the results are less constant in arterio-sclerosis.

In twenty-five cases abundant diuresis resulted; at least eighty ounces of urine were passed, usually one hundred or more, in the twenty-four or forty-eight hours subsequent to beginning the treatment. As soon as the treatment was stopped the amount of urine fell off to what it had been before the administration of the diuretic. Prof. Sée, therefore, considers lactose to be not only the most efficient diuretic, but also the least harmful. If milk is used and two quarts only are taken, diuresis follows; if four quarts of milk, containing six and one half ounces of sugar of milk, marked glycosuria is produced; at the same time there is considerable excretion of urea, indicating a destruction of the albuminates. With the sugar alone these disadvantages may be avoided, for three and a quarter ounces of milk sugar in water will set up a copious diuresis, such as we cannot be sure of having from even four or five quarts of milk.

The polyuria resulting from this treatment surpasses that from all other methods; the amount of urine rises rapidly to two, two and one-half, usually to three or three and one-half quarts, and even to four or four and one-half quarts on the third day. After this it remains at that point, or drops to two and one-half quarts for some days. After a few days the same treatment may be employed to repeat the diuresis.

It is fair to say that this action of lactose may be relied upon in cases of cardiac dropsy, but in those of renal origin its effects are slight. In cardiac disease it never fails unless the kidneys are diseased and the amount of albumin is considerable. When the amount of albumin is small the result is favorable, from which it may perhaps be inferred that there is present only a simple venous congestion.

It is suggested that the diuresis may serve as an indication of the condition of the kidneys. Various conditions may affect the diuresis; sometimes diarrhoea occurs, and this diminishes the amount of urine, or the patient may have been subject to profuse sweating, which would also lessen the quantity of urine.

As a rule the remedy is well borne. It may be prescribed for eight or ten days and then omitted for a few days and again renewed. If the simple solution is not well tolerated, brandy or peppermint may be added to it. All other liquids should be reduced in amount or omitted while this treatment is pursued.

This method presents great advantages over many others, and the patient may partake of any food, a meat diet, if the physician so desires. Prof. Sée considers that the physiological action of lactose is upon the kidneys, since it does not exert any influence upon the circulation. He classes it with caffeine, as he believes that caffeine acts upon the kidneys only, and not through the circulation, as do digitalis and strophanthus.

Lactose is regarded as superior to caffeine, as it does not affect the brain and nervous system. —*L'Union Médicale, American Journal of the Medical Sciences.*

### EPILEPSY TREATED BY AMYL NITRITE.

Having read a few weeks ago in this journal Dr. Woods' treatment of epilepsy, and being called to a very severe fit in a young man who has been an epileptic from birth, and whose mind has been so impaired that, though 21 years old, he is unable to read, write, or dress himself, I determined to try amyl nitrite. After inhalation of one capsule, the convulsion ceased, and in about twenty minutes the patient was himself again, the insensibility which always followed the fits being almost nullified. Since then the drug has been tried four times, and each time with success; if administered at the commencement of the fit, the latter was aborted, and the insensibility almost completely prevented. This patient is in the habit of having, on an average, a fit daily; and frequently a succession of fits—status epilepticus. He has been a patient for years at the Epileptic Hospital, Queen Square, and has been taking bromides daily, but apparently with no effect. I hope soon to be able to give an account of the action of nitro-glycerin tablets, which he is at present tak-

ing, in the hope that they will render the fits less frequent.

I believe that hitherto the amyl nitrite has been used only in the status epilepticus, but it appears to me to be also useful in severe single fits. The *rationale* of its action has not, I think, been worked out, but obviously would seem to be due to its dilating influence on the cerebral arteries contracted during the convulsions.—J. P. PARKINSON, M.B., in the *British Med. Journal*.

#### THE DRINK QUESTION IN FRANCE.

The recent Anti-Alcohol Congress in Paris showed that the dram shops of Paris have risen since 1880 from 24,000 to 29,900. In thirty years the consumption of alcohol has been trebled, and as much as 36,000,000 galls. have been manufactured out of potatoes for the French market. This shows an average yearly consumption of over 12 quarts per adult man. The consumption of alcohol doubled between 1875 and 1885. The Congress voted a resolution that inebriates should be treated as mad, and that prison hospitals should be created for them. It was also resolved that the Governments of the world should be asked to impose a prohibitive duty on alcohol, and exempt from duty tea, coffee, and other ingredients for temperance drinks.

#### THE MILK OF TUBERCULOUS COWS.

At the Congress on Tuberculosis held in Paris in July, 1888, it was unanimously conceded that the milk of tuberculous cows was dangerous for use. Some held that it was only so when the udder was affected with tubercular disease; but as it is impossible for milkers and dairymen always to diagnose this, they unanimously recommended that all milk should be boiled. There was some difference of opinion as to the use of meat of tuberculous cows. Dr. Trocart held that if the disease is localized the flesh does not contain any bacilli. Dr. Arlving contended that in his experience virulent bacilli existed in the muscles of tubercularized animals in one-fifth of the cases. He desired to see tuberculosis inscribed among the infectious diseases, and thought the flesh of tuberculous animals should be prohibited as food till means were found to render it harmless. He suggested the creation of a permanent committee to carry out, in cities and towns, the realization of a complete sanitary organization. It was learned that in Paris, Brussels, Constantinople and other large cities the meat is condemned if the disease is generalized and the cattle emaciated. After a lengthened discussion, which brought out a great many interesting facts in relation to the etiology of tuberculosis and its communicability, the following resolution was

voted upon and carried almost unanimously: "It is necessary to carry out, by all possible means, including indemnification of those interested, the general application of the principles of seizure and total destruction of all meat coming from tuberculous animals, whatever may be the gravity of specific lesions found in those animals." Chauveau, President of the Congress, suggested that simple instructions should be printed and widely distributed throughout the cities and towns and in the country, explaining the danger of drinking tuberculous milk and eating tuberculous meat, and the ways of rendering the meat inert. Though much has yet to be learned on this vital question, enough proof has already been adduced to warrant the adoption of active measures towards the extermination of tuberculous cattle. Is not the Government called upon to deal with tuberculosis as it does with pleuro-pneumonia?—*Montreal Medical Journal*.

#### TYPHOID FEVER—ANTIPYRIN RASH.

In the case of a girl of 25 years suffering from severe typhoid fever, with the temperature for several nights at 105°, antifebrin was given without marked effect, and subsequently antipyrin. The latter reduced the temperature for a time, but after two doses had been taken a rash broke out on the face and neck. It did not resemble urticaria or measles. The forehead became of a pale red color, like the skin of a newborn baby, and there was slight puffiness of the lids. On the neck the pale red patches were somewhat discrete. By next morning all the rash had disappeared. Antipyretics were abandoned, when, after two days, the temperature fell to 102° and 101°, and the symptoms improved. The action of antipyrin in producing rashes seems to be very common, though so far I have seen but these two cases. The journals contain many such records. The rashes are described as measly, erythematous, or urticarious.—MONTREAL HOSP. REP., *Montreal Med. Journal*.

#### INGESTION OF ASCITIC LIQUID.

Probably the most remarkable potation on record is that of an inmate of the hospital at Obernay, France, who, after being tapped for the fifty-third time, took advantage of an opportunity to drink off about eight ounces of the product of his own peritoneum, and with apparent relish. But what is more and stranger, his dropsy has not recurred within the year that has elapsed since he took the beverage, the œdema has been reduced, and he has been enabled to resume his employment. Dr. Duhamel is responsible for this narration in the *Gazette Médicale de Strasbourg*.

## SOCIETY PROCEEDINGS.

## Association of American Physicians.

*Fourth Annual Meeting, held in the Army Medical Museum and Library, Washington, D. C.,*

*September 18, 19 and 20, 1889.*

*(Concluded from p. 465.)*

DR. D. W. PRENTISS, of Washington, reported

A REMARKABLE CASE OF SLOW PULSE EXTENDING OVER A PERIOD OF NEARLY TWO YEARS.

G. W. P., white male, carpenter, æt. 54 years. Has always been healthy; the only illness he remembers is neuralgia of stomach fourteen years ago. The only injury ever received was a fall a distance of 15 feet and striking on his feet, when 19 years old. Ten years ago a brick fell upon his head, cutting the scalp but causing no serious injury. Never had any form of venereal disease. Always temperate in the use of alcohol but not in the use of tobacco. He has been under the observation of the writer for sixteen years, but had never been attended professionally until present illness.

December 13, 1887, after working some time in a malarial locality, he began to have weak spells, and several times fainted on lifting heavy weights. Examination showed no well-defined disease. No fever, mind clear, pulse 36. Urine normal. No organic disease of heart discovered, the systole was full and strong, diastole greatly prolonged. Between December 13, 1887, and January 20, 1888, the pulse ranged from 22 to 76. During this time there were frequent attacks of syncope. During one fainting attack he fell down stairs. At another time fell out of a chair, remaining unconscious about a minute. After January 20, his pulse had reached 76, he had no more fainting spells. In March he resumed work. October 2, 1888, he had a relapse with the same symptoms as in previous attack. From this date to April 15, 1889, the pulse ranged from 15 to 44 per minute. The fainting attacks continued throughout this time, occasionally very severe. He improved to a certain extent, but about August 29 he began to have a return of the old symptoms. During the fainting spells the pulse fell to 12 or 15°. Between August 5 and September 18, the pulse ranged between 12 and 38° per minute, and between August 10 and August 15, it did not rise above 14° per minute. The temperature during this time was between 94.5° and 97°. The patient improved somewhat after August 15 and September 18 was well enough to present himself for examination before the Association.

The "spells" referred to, were described. They came on without warning, often without apparent cause, sometimes often exhaustive. He faints,

losing consciousness. They last from a few seconds to half an hour. Breathing gasping and slow. Face and hands, first pale, then dark and purplish. There is no pain. He has great confidence in the bromide of ammonium, which he thinks controls the attacks. The treatment of the case from the first has been rest in bed, tonics, stimulants, electricity and bromide of ammonium together with supporting diet. The tonics used were strychnia, opium and iron with belladonna. Digitalis was tried but made him worse. Nitroglycerine seemed to help for five doses, but later caused distress. Convallaria and strophanthus were tried with like result. The drug which appeared to give the most relief was bromide of ammonium, given in doses of 1 gram (15 grains) three times a day, and extra doses when paroxysms threatened.

The most interesting question in this case turns upon the pathology. What is the cause of the retarded action of the heart? The causes which may produce slow pulse may be classified as follows:

1. Disease or injury of the nerve centers, producing either irritation of the pneumogastric or paralysis of the sympathetic (acceleration) nerves of the heart.
2. Disease or injury of the pneumogastric nerve increasing its irritability.
3. Disease or injury of the sympathetic nerves of the heart—paralyzing them.
4. Disease of the cardiac ganglia by which the influence of the pneumogastric preponderates.
5. Disease of the heart muscle (degeneration) whereby it fails to respond to the normal stimulus.
6. Action of poisons, as of lead or tobacco, either on nerve endings or nerve centers.

In this case it is difficult to say to which of these divisions it belongs. There are no symptoms to indicate any form of disease of the nerve centers. There is no evidence of disease of the nerves themselves, nor has any organic disease of the heart been discovered. There is left only the action of certain poisons, and the question arises whether or not in some obscure way the conditions may not be due to tobacco poisoning from excessive smoking. Another possibility is malarial poisoning. The attacks first appeared while he was working in a malarial district, and in the summer of 1888 he had intermittent fever. These considerations make it probable that there is paralysis of the accelerator nerves and not an irritation of the vagus. The symptoms are due solely to defective circulation.

In many of the cases collected in connection with this report, the pathological appearances were a result of the slow pulse rather than a cause.

Abstracts were given of 55 cases of slow pulse

of which the following is a brief analysis as to causes : 1. Fracture or dislocation of cervical vertebrae, 9 cases. 2. Disease of brain, 9 cases. 3. Cerebral syphilis, 2 cases. 4. Sunstroke, 1 case. 5. Ossification of aorta valves and coronary arteries, 2 cases. 6. Starvation, exhaustion, loss of sleep, convalescence, 3 cases. 7. Epilepsy and epileptoid disease, 9 cases. 8. Heart disease, 6 cases. 9. Lead poisoning, poisoning by salt fish, pernicious fever, 3 cases. 10. Nervous shock, cholera morbus, 2 cases and 11, not stated, 9 cases.

#### THURSDAY—MORNING SESSION.

DR. FREDERICK P. HENRY, of Philadelphia, read a paper on the

#### RELATION BETWEEN CHLOROSIS, SIMPLE ANÆMIA AND PERNICIOUS ANÆMIA.

The discussion of the relation between chlorosis, simple anæmia, pernicious anæmia, etc., may be divided into three heads : 1. Are they separate diseases? 2. Are they of kindred nature? 3. Are they different stages of one affection? Pernicious anæmia is first considered, because the determination of its status is of fundamental importance. It is admitted by all that the clinical features of this disease are common to a number of affections, especially cancer and atrophy of gastric glands; but those who argue most forcibly in favor of its independent nature exclude from the category of pernicious anæmia all cases in which an anatomical lesion of any organ is found. This appears to me unscientific, for an independent disease is one which rests upon a constant anatomical basis or is invariably produced by the same specific agent. Hunter has endeavored to establish pernicious anæmia as an independent disease by the demonstration of an excess of iron in the liver in cases of that affection. He regards this as the essential anatomical feature of pernicious anæmia. The work of Hunter is of great value, and certainly demonstrates the existence of an excessive hæmolytic in that disease. In my opinion, however, this excessive hæmolytic is a consequence of defective hæmogenesis, for certain facts show the red corpuscles of pernicious anæmia to be abnormally weak and perishable. Chlorosis is universally admitted to be due to defective hæmogenesis, and, therefore, I regard it and pernicious anæmia as closely related affections. Transitions from the one affection to the other have also been observed by myself and others.

Conclusions : (1) That pernicious anæmia is a process, not a disease ; (2) that it is closely related to chlorosis ; (3) that it may be the terminal stage of other diseases, and especially of cancer of the stomach and atrophy of the gastric glands.

Leucocythæmia and Hodgkin's disease, in that

they are always associated with lesions of the blood-making organs—spleen, lymph glands, bone marrow, etc.—are independent diseases, or rather, different stages of the same disease, for several cases are recorded in which an undoubted transition from one to the other has been observed.

DR. F. FORCHEIMER, of Cincinnati, read a paper on

#### THE RELATIONS OF ANÆMIA TO CHLOROSIS.

He referred to the confusion which existed in regard to the definition of the two diseases. Immermann says that we are justified in stating that anæmia is that condition in which there is a diminution of red corpuscles as well as of the albumens of the plasma in the blood (hypalbuminosis). Strümpell considers that "the essential element in anæmia is therefore a diminution in the number of red corpuscles or so-called oligocythæmia," and states further that "oligocythæmia is not invariably accompanied by a diminution in the amount of serum albumen (by which means plasma-hypalbuminosis)." Going on it is found that anæmia or oligæmia vera really means a diminution of the whole quantity of the blood, and that this condition can be divided into hydræmia, oligocythæmia, oligæmia sivea and oligæmia hypalbuminosa. We have three representative definitions; the one broad and general, including a diminution of any one or all of the constituents of the blood; a second, in which hypalbuminosis and oligocythæmia are the principal if not the only factors; and a third which makes oligocythæmia alone the characteristic feature. From a purely practical standpoint the latter seems the best.

The same confusion in regard to definition is met with in a consideration of chlorosis. Duncan (1867) was, however, probably the first to make the distinctive feature, oligochromæmia, characteristic for chlorosis—that is, in chlorosis we find the individual red corpuscle deficient in hæmoglobin. Unfortunately for this definition the term chlorosis is to be looked upon as an essentially clinical one; it is not going too far to state that by far the great majority of reported cases of chlorosis are not chlorosis at all. Another difficulty is that both oligocythæmia and oligochromæmia may occur in the same individual, so that the term chloranæmia is justified by observation of existing conditions. It is more than probable that anæmia is a forerunner of chlorosis in a great many instances, and possibly a number of cases occur in which there is a combination of both conditions.

Almost any cause put down for anæmia will hold good for chlorosis. Sex, age, a peculiar composition of the blood and certain vascular anomalies are held to be especially characteristic for chlorosis. The two latter are the only ones to be found in chlorosis. The process of sexual

development is looked to as the time of most common occurrence of chlorosis. This age also produces a great number of cases of anæmia, but children and old people are subject to anæmia and practically excluded from chlorosis. The greatest number of cases occur between the ages of 15 and 25 years, decidedly after the time of first menstruation. Furthermore, an anæmic constitution is a strong predisposing cause for chlorosis.

The clinical characteristic of chlorosis lies in the peculiar changes in the blood. In anæmia the red corpuscles as well as the albumens of the plasma are reduced in quantity, and frequently there is production of a greater number of smaller corpuscles (microcytes). As a result of the reduction of the number of red corpuscles the hæmoglobin is correspondingly reduced in quantity. In pure chlorosis the number of red corpuscles is not diminished and a tendency to the production of larger red corpuscles (megalocytes) is especially well marked. These changes are, however, not sufficiently characteristic to establish a diagnosis. It is also found that the proportion of hæmoglobin in each corpuscle is diminished. It has been said that in anæmia there is always hypalbuminosis, while in chlorosis this is absent, but this has not yet been positively proven.

One respect in which chlorosis is said to differ materially if not absolutely from anæmia consists in the pathological changes, first described by Virchow. These are narrowing of the lumen of the aorta and larger arteries as well as thinning of their walls. The heart is sometimes small, sometimes hypertrophied. This view would permit us to state that chlorosis is always congenital, in some cases latent for years, while anæmia in most cases is acquired. Many objections have been urged against this view.

The relation of the symptoms of anæmia to chlorosis depends upon the conditions of the blood and the anatomical substrata. Given a case of anæmia in which there is only a reduction of hæmoglobin as a result of oligocythæmia and a case of chlorosis in which there is a reduction of hæmoglobin as a result of oligochromæmia, and metabolism in both these cases will be approximately the same; but if in anæmia we have oligocythæmia as well as hypalbuminosis, which is said to coexist in the majority of cases, the metabolism must be different from that of a pure case of oligocythæmia. As a result of a reduction of hæmoglobin there is simply reduction in the process of oxidation; at the same time the waste products are carried off and sufficient albuminous food is carried to the tissues by the plasma of the blood, which is unchanged. Hypalbuminosis and oligocythæmia produce an entirely different result. We have the same factor, suboxidation, but we have in addition deficiency of supply. In mild cases of anæmia, there is produced a loss of

weight; in severe cases, the condition called marasmus. In chlorosis very little if any loss of weight occurs; very frequently the opposite condition is brought about by too great supply and by the presence of too much  $\text{CO}_2$ , preventing decomposition of fats. When anæmia is associated with chlorosis, we have a very unfortunate combination, especially if there is a great amount of hypalbuminosis.

Unless we believe that the anatomical lesions of Virchow belong to chlorosis, there exists no difference between the symptoms of chlorosis and anæmia.

The therapeutic relations of the two diseases must be considered. While the indiscriminate use of iron in anæmia must be deprecated, yet upon the whole iron is just as much looked upon as a specific in anæmia as in chlorosis. Where in anæmia we try to remove the cause and institute causal treatment, we are satisfied in chlorosis with removing the symptom which is the essential of the disease. It has been repeatedly demonstrated that the removal of this essential symptom is followed temporarily by complete recovery. Whereas, in anæmia, treatment is followed by complete recovery or complete failure, iron in chlorosis will always result in amelioration, even if the tendency to relapse cannot be removed. There are few cases of chlorosis, even those with the lesions of Virchow, that are not benefited by the administration of iron in sufficient quantity. In a great many cases of anæmia, the use of iron would be followed by negative or by bad results.

DR. WILLIAM OSLER, of Baltimore, took issue with Dr. Henry in regard to chlorosis. He held that chlorosis is absolutely distinct from pernicious anæmia, for the following reasons: 1. The sex; he had never seen chlorosis in the male. 2. The pathological conditions. He regarded thus the hyperplasia of the heart and great vessels as a specific anatomical distinction of a certain number of cases. 3. The character of the blood. He considered the diminution of the percentage of hæmoglobin a distinctive feature of chlorosis. 4. Curability. Although in chlorosis there is a tendency to relapse, each given attack can be cured if sufficiently large doses of iron are employed.

DR. FRANCIS P. KINNICUTT, of New York, agreed as to the lack of relation between chlorosis and pernicious anæmia. He had never seen true chlorosis in the male. All his cases of pernicious anæmia, on the other hand, with one or two exceptions, had occurred in males. He agreed with Dr. Henry in regard to the relationship between Hodgkin's disease and true leukæmia.

DR. W. W. JOHNSTON, of Washington, thought that a study of certain anæmias which are met with in women will throw light upon the association of anæmia with diseases of the intestinal glands and gastric tubules. The explanation of

the chronic anæmias of parturition is probably the continued pressure upon the intestinal tube, causing a long starvation lasting nearly a year. This seems to produce an actual organic change in the intestinal glands. Several illustrative cases were cited.

DR. WILLIAM PEPPER, of Philadelphia, agreed with Dr. Osler in regard to the relation between true anæmia and chlorosis and progressive pernicious anæmia, so called. He was not prepared to admit the analogy between true chlorosis and progressive pernicious anæmia. The conditions of the blood are widely antagonistic in these two affections. The clinical differences are also very marked. In the present state of knowledge it is probably wiser to consider essential anæmia as an independent affection.

DR. FREDERICK P. HENRY, of Philadelphia, thought that the definition of chlorosis given by Dr. Osler could not be maintained; that is, there is always a diminution of hæmoglobin, with a nearly normal number of red corpuscles. The arguments that he had advanced were based entirely upon personal observations. While chlorosis is readily relieved by treatment in the early stages, yet, if it is neglected, the chlorosis may become more intense and may present the appearances of pernicious anæmia.

DR. S. WEIR MITCHELL, of Philadelphia, read a paper on

#### SUBJECTIVE FALSE SENSATION OF COLD, CONSIDERED AS A SYMPTOM.

The speaker had met with many cases where a feeling of cold is complained of in members which do not present any objective changes in temperature. These may be placed in three classes: 1. Those due to a central cause. 2. Those due to neuritis. 3. Those whose origin is at present inexplicable or due to hysteria. A number of cases exhibiting this symptom to an extreme degree were reported. In the first case a marked sensation of cold involving the left side of the body followed an injury to the head. Three or four cases were referred to coming in the second class. The sensation of cold involved the posterior part of the legs, the back or buttocks. In all these cases there was either neuritis at the time or it developed subsequently. When this symptom is noted neuritis may be expected. Two cases belonging to the third group were described. One was an elderly individual with no signs of hysteria; the other was a case of young woman with marked hysterical symptoms.

DR. G. M. GARLAND, of Boston, read a paper on

#### GASTRIC NEURASTHENIA.

Three cases of vomitus nervosus were reported:

*Case 1.*—Miss S. began at the age of 2 years to have sudden attacks of vomiting. These recurred at irregular intervals until the time of her death.

The attacks lasted twenty-four hours and it required a week for the child to recover her strength. At the age of 20 she began to have excessive muscular twitchings with the attacks. Two years later she began to have severe headaches. These gradually merged into one steady ache. January 2, 1884, the author saw the patient suffering from intense headache and slight twitching of arms and legs. Vomiting appeared the next day, causing intense burning of the throat from the intensely acid character of the matter vomited. After four days she gradually improved and entirely recovered. November 12, 1884, the patient was again seized with headache. November 15th vomiting and twitching began. She gradually improved until December 2d, when all the symptoms returned and continued until her death, December 13th. Urine was normal until a few days before death, when it contained a trace of albumin, but no casts. At the autopsy no marked organic change was found in any part of the body.

*Case 2.*—Miss S., 22 years old, first seen September 19, 1888. She was in bed with headache, poor appetite, constipation and weakness. Pulse, temperature and urine normal. Some nausea. Vomiting appeared in a few days. She was fed exclusively by the rectum for three weeks, but the vomiting persisted and there was severe burning along the entire œsophagus. At times the urine was scanty, but never contained albumen. She gradually improved, but is not as strong as before her illness.

*Case 3.*—Miss D., aged 43 years, had been subject to bilious headaches. During the summer of 1888 she had a severe attack of vomiting and she was very ill for several weeks. During the following September, as a result of anxiety, the appetite left her and the nausea returned. She, however, did not vomit.

#### AFTERNOON SESSION.

DR. JOHN H. MUSSER, of Philadelphia, read a paper on

#### PRIMARY CANCER OF THE GALL BLADDER AND DUCTS.

The speaker, after describing two cases of this affection that had come under his observation, reviewed the cases that had been reported and presented the following conclusions:

Primary cancer of the gall bladder is not so rare as is generally believed. It occurs in the female nearly three times as often as in the male. A large number (57 per cent.) of the cases occur under the age of 60. Gall stones are an exciting cause, especially in persons predisposed to the affection. The organ is generally not much enlarged save as the result of secondary processes. Metastasis is not widespread. By continuity of structure neighboring organs are involved. Ad-

hesions to adjacent organs with ulceration and perforation are not uncommon. Pain, jaundice and the presence of a tumor are the most common phenomena. With them are associated anæmia, cachexia, vomiting, constipation or diarrhœa and ascites. Pain was present in 62 per cent. of the cases, at first ill-defined, then becoming localized to the right hypochondrium and lancinating in character. Jaundice was present in 69 per cent., gradually increasing in degree. In some cases, however, it was intermittent. Tumor was noted in 63 per cent. The tumor was hard, firm, painful, and generally movable with respiration. The progress of the disease is always continuous. Some extraordinary cases are reported in which there was temporary cessation in the progress of the disease. Death results from exhaustion; frequently from peritonitis. In some cases from metastasis to other organs; in some from biliary obstruction. In eight cases death was due to cholæmia. The duration of the disease is short, the average being six and two-thirds months. The progress is rapid after complete occlusion of the biliary passages or evidence of inflammation of the biliary passages has developed.

DR. HENRY FORMAD, of Philadelphia, read a paper on *The Anatomical and Physiological Relations of Lesions of the Heart and Kidneys*. The paper was based upon the post-mortem study of 300 cases observed in public and private practice.

DR. P. G. ROBINSON, of St. Louis, read a paper on

#### THE CONTAGIUM OF DIPHTHERIA.

Diphtheria is an acute infectious disease, doubtless due to a living organism (microbe) the exact identity of which cannot yet be regarded as settled.

Primarily a local affection, the system becomes secondarily and generally infected through absorption of a poison generated at the primary and localized seat of inoculation.

The modes of infection are numerous, the contagium being directly transferred by contact, in a dry state through the air for limited distances, in foul clothing, in polluted food and drink, milk probably being a prolific source of infection.

The most difficult problem to solve is that which relates to the conditions most favorable to the growth and development of the germs and the propagation of the disease.

While, strictly speaking, diphtheria can hardly be called a filth disease, since it prevails often to a very limited extent in those localities whose hygienic surroundings are apparently the worst, yet certain kinds of filthy accumulations, as the ordure of animals, notably the refuse from cowsheds and dairies, seem to furnish the most favorable conditions for the culture of this particular germ.

Until this problem can be solved and the life history and habitat of the diphtheritic germ is understood, no definite plan can be formulated

for the arrest of the contagium nor for the hopeful treatment of the disease.

#### FRIDAY MORNING.

The following officers were elected: President, Dr. S. C. Busey, Washington; 1st Vice-President, Dr. Wm. Pepper, Philadelphia; 2nd Vice-President, Dr. Henry M. Lyman, Chicago; Recorder, Dr. I. Minis Hays, Philadelphia; Secretary, Dr. Henry Hun, Albany; Treasurer, Dr. W. W. Johnston, Washington; Member of Council, Dr. G. Baumgarten, St. Louis; Representative on Executive Committee of Congress of American Physicians and Surgeons, Dr. Wm. Pepper, Philadelphia.

The following members were elected: Drs. Wm. G. Thompson, Wm. H. Thomson, J. West Roosevelt, New York; Charles Carey, Charles G. Stockton, Buffalo; Victor C. Vaughn, Heneage Gibbes, Ann Arbor; Charles W. Purdy, Chicago; Starling Loving, Columbus, O.; W. H. Geddings, Aikens, S. C.; Wm. C. Dabney, Charlottesville, Va.; B. F. Westbrook, Brooklyn, and Henry P. Walcott, Cambridge, Mass.

The date of the next meeting to be between May 20 and June 15, 1890.

DR. JAMES J. PUTNAM, of Boston, read a paper entitled

#### A SUPPLEMENTARY INQUIRY INTO THE FREQUENCY WITH WHICH LEAD IS FOUND IN THE URINE.

The paper embodied further researches as to the frequency with which traces of lead are found in the urine of persons in good health, or not presenting the classical symptoms of lead poisoning; and discussed the propriety of enlarging our clinical conception of that disease. A table was shown in which the results of the present investigation were combined with those reported upon two years ago, which may be summarized as follows: The urines of 68 persons, either presenting no symptoms (healthy medical students) or only symptoms of specific or local disease (phthisis, pleurisy, local injuries, etc.) were found by Dr. A. M. Comey and Dr. C. R. Worcester, to contain lead in the proportion of about 17 per cent.; while those of another group of 125 persons, presenting various symptoms of disease, such as it was thought might possibly be due in part to lead poisoning, contained lead in the proportion of 50 per cent. The largest sub-group of this latter class embraced 36 cases, not strictly homogeneous, but made up of chronic or sub-chronic affections of the spinal cord and peripheral nerves. One (typical) fatal case of this sub-group was analyzed at some length, and the results of the microscopic examination of the spinal cord and nerves were reported upon. The case was that of a carriage painter, who suffered for some years with progressive anæmia and general emaciation, and for the two years preceding his

death with weakness, paræsthesia and impairment of sensibility with exaggerated tendon reflexes and extensor spasms, increasing finally to complete paraplegia. Lead had been found in the urine three times, but the patient had never presented "a blue line," characteristic of paralysis, encephalopathic symptoms, or colic, though the bowels had been obstinately constipated for years. The morbid changes found after death, besides the signs of general anæmia, were those of combined antero-posterior and lateral sclerosis of the cord, on which at the last, a subacute process of diffuse destructive softening had engrafted itself.

This latter process, which was characterized by the presence of a dense infiltration of granule cells and by a breaking down of the nerve tubes, so as to form round or oval cavities, such as have often been described, extended throughout the length of the cord, occupying the position of the sclerosed system traits of the adjoining tissue. The nerve roots were effected though to a less degree than the cord; the posterior much more than the anterior. The acuter process was at its height in the dorsal region. The gray matter was also affected, apparently in proportion to the severity of the secondary acute change, *i. e.*, most severely in the dorsal region. The smaller arteries were here and there thickened. The peripheral nerves were degenerated, but only to a moderate degree.

It was not assumed that these changes in the cord were due to lead as a specific poison, though at the same time the evidence is that such myelitic changes as lead does set up are diffuse in character and not coördinated with the typical peripheral nerve degeneration. It was, however, thought more probable, in view of the circumstances under which such pathological processes had been seen in other cases, that the lead acted, if at all, by inducing a general and—through the thickening of the vessels—a local anæmia, thus intensifying the effects of other influences, of which one might be an hereditary tendency.

Another case was cited to show that lead in drinking water may cause outbreaks of acute indigestion in children, while other children exposed to the same influence may be wholly unaffected.

A number of observations made on Boston drinking water by Dr. E. M. Greene were reported, showing the frequency with which lead is present and the length of time required to wholly rid a pipe of its presence.

DR. HAROLD C. ERNST, of Jamaica Plains, Mass., read a paper entitled

#### HOW FAR MAY A COW BE TUBERCULOUS BEFORE THE MILK BECOMES DANGEROUS AS A FOOD SUPPLY?

The observations which he reported were made at the instance of the Massachusetts Society for

the Promotion of Agriculture. The surroundings of the animals used were prepared in the most careful manner. One hundred and fourteen samples of milk were examined for the bacillus. These were obtained from thirty-six cows suffering with tuberculosis of some organ other than the udder. Seventeen samples were found to contain tubercle bacilli. These seventeen specimens came from ten cows. The cream was found to contain bacilli as often as the milk. The bacilli were present with a fair degree of constancy.

Well animals were then inoculated with the result of inducing the disease in 50 per cent. of the cases treated. Feeding experiments were also made with the result of inducing the disease in a number of calves and young pigs. The following conclusions were presented: 1, and emphatically, that milk from cows affected with tuberculosis in any part of the body may contain the virus of the disease. 2. That the virus is present whether there is disease of the udder or not. 3. That there is no ground for the assertion that there must be a lesion of the udder before the milk can contain the infection of tuberculosis. 4. That, on the contrary, the bacilli of tuberculosis are present and active in a very large proportion of cases in the milk of cows affected with tuberculosis, but with no discoverable lesion of the udder.

DR. E. L. TRUDEAU, of Saranac Lake, read a paper on

#### HOT AIR INHALATIONS IN PULMONARY TUBERCULOSIS.

The paper presented a brief clinical history of four cases treated during periods varying from one to four months by Weigert's method. This was considered as secondary and only as a basis for the bacteriological study which is left to answer the claim of specificity made for the method. The question to be answered is whether breathing of hot air can prevent the growth of the tubercle bacillus in the lungs of living individuals. The clinical evidence obtained brings out no positive proof in favor of the treatment. From the bacteriological research the following notes are made: In all the cases the bacillus which was present before the treatment remained in the sputum, and no effect was produced upon that important element of the disease. The claim of diminished virulence was tested by inoculations made on rabbits before, during and after the treatment. The sputum of one of the patients who improved was found, fifteen weeks after the uninterrupted daily breathing of hot air, to produce tuberculosis in the animals injected as promptly, and to a similar extent, as that injected before the treatment had been instituted.

*Conclusions:*—1. The therapeutic value of hot air inhalations in phthisis is doubtful. 2. The evidence obtained by bacteriological study of the

cases recorded does not confirm the assumption that inhalations of heated air can either prevent the growth of the tubercle bacillus in the lungs of living individuals, or diminish the virulence of this microbe when it has gained access to them.

## NECROLOGY.

### Dr. Addinell Hewson.

DR. ADDINELL HEWSON, of Philadelphia, a member of the Association in 1855, died September 11, in his 66th year. He was descended by a medical line of ancestry, being the fourth in descent from an eminent London surgeon. He was carefully educated at home, and at Dublin, after taking his medical degree at Jefferson College, which was in 1850. He was eminent in surgery as well as editorial and literary work. He was appointed visiting surgeon to the Pennsylvania hospital in 1861.

### Ex-Surgeon General Joseph Beale.

EX-SURGEON GENERAL JOSEPH BEALE, with relative rank of Commodore U. S. N., died on the 24th ult., at his residence in Philadelphia. Dr. Beale was born December 30, 1814, and received his classical and medical education in the University of Pennsylvania, from which institution he graduated in 1836. He practiced his profession for one year, at the end of which period he entered the United States navy as Assistant Surgeon, and afterward rose to the position of Surgeon General of the navy, to which he was appointed in December, 1873. He was placed on the retired list in 1876.

### Dr. S. O. Habershon.

DR. S. O. HABERSHON, the well-known English medical author, died in London, on the 22d ult., at the age of 64 years. His books on the diseases of the abdomen, passed through several editions, of which two appeared in this country. He was senior physician to Guy's hospital. He was a philanthropist and prominent in religious undertakings.

### Deaths of Eminent Foreign Medical Men.

*The Lancet* announces the death of the following eminent foreign medical men: Dr. Jacobson, professor of chemistry in the University of Rostock; Dr. Anthon Geuter, professor of chemistry in the University of Jena; Dr. Anton Nuhn, honorary professor of anatomy in the University of Heidelberg; Dr. Josey Tieftrunk, of Prague, formerly body physician to the Emperor of Aus-

tria; Dr. Franz Hellwig, the botanist attached to the German New Guinea expedition, and Dr. Wasseige, professor of midwifery in the University of Liege.

## MISCELLANY.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.—We again call attention to the meeting of this Association, which will convene at Brooklyn Institute, Washington and Concord streets, Brooklyn, October 22, 23, 24, 25. Hon. Alfred C. Chapin, Mayor, will deliver the Address of Welcome on behalf of the city. That on behalf of the medical profession will be delivered by Dr. Alexander Hutchins. The topics to be considered are as follows:

1. The Causes and Prevention of Infant Mortality.
2. Railway Sanitation (heating, ventilation, water supply, water-closets, carrying of passengers with infectious diseases).
3. Steam-ship Sanitation.
4. Methods of Scientific Cooking.
5. Yellow Fever (unprotected avenues, local protection, the proper procedure of local health authorities in case of an outbreak of yellow fever).
6. The Prevention and Restriction of Tuberculosis in Man.
7. Methods of Prevention of Diphtheria, with Results of such Methods.
8. How far should Health Authorities be Permitted to Apply known Preventive Methods for the Control of Diphtheria?
9. Compulsory Vaccination.
10. Sanitation of Asylums, Jails and other Eleemosynary Institutions.

THE INTERNATIONAL DENTAL CONGRESS.—Drs. E. B. Ward and J. A. Swasey, delegates from Chicago to the International Dental Congress at Paris, have returned, and say it is a certainty that the meeting of the Congress in 1892 will be held in Chicago. A letter from Mayor Cregier inviting the Congress to come to Chicago, and one from Ferd Peck, tendering the auditorium hall, were presented to the Congress and met a cordial reception, particularly from the French delegates. Dr. Ward says the belief was quite general among the delegates that the world's fair would be held in Chicago in 1892, and they favored holding the International Dental Congress here at the same time.

GERMAN CODE OF ETHICS.—At the seventeenth Congress of German physicians held recently at Brunswick, the following resolutions were passed:

1. Every kind of public laudation, whether it proceeds from the physician in question himself or from others, and continued advertising in public papers are to be reprobated.
2. The designation "specialist," for puffing purposes, is to be reprobated.
3. The public offering of medical assistance gratis, underbidding in concluding contracts in sick societies and the like, offering advantages of any kind to a third person in order to procure practice, are inadmissible. The designations "klinik" and "poliklinik" (hospital) belong exclusively to institutions which serve the purpose of instruction in connection with universities.
4. The ordering and recommending of secret remedies are inadmissible.
5. Any attempt of any kind on the part of a physician to intrude upon the practice of another is dishonorable, especially in the case of one who has acted as substitute or in consultation. A practitioner must by no means undertake the treatment of a case without the ex-

press consent of the previous physician. A specialist called in for a definite part of the treatment must strictly confine himself to that.

6. No physician is at liberty to make disparaging remarks to others about another physician.

**TRI-STATE MEDICAL ASSOCIATION.**—The following papers have been promised for the meeting of the Tri-State Medical Association:

"Demonstrations with the Microscope," Prof. James A. Reeves, Chattanooga. "Stricture," Prof. Daniel H. Howell, Atlanta, Ga. "A Case of Typhoid Fever with Subnormal Temperature and Subnormal Pulse," Dr. A. S. Wiltse, Kismet, Tenn. "A Plea for the Medical Education of Females," Dr. Chas. P. Gordon, Dalton, Ga. "Choleo Cystotomy, with a Case," Dr. E. E. Kerr, Chattanooga. Report of a Case, Dr. Wm. T. Blackford, Graysville, Ga. "Physiology of the Heart and its Valves," Dr. W. L. Gahagan, Chattanooga. "Relation of the Specialist to the General Practitioner," Dr. F. W. Skillern, Pikeville, Tenn. "Some Points in the Diagnosis of Skin Diseases," Prof. E. A. Cobleigh, Chattanooga. "Imaginary Foreign Bodies in the Throat," Dr. Max Thorner, Cincinnati, O. "Antiseptic Midwifery," Prof. F. W. McRae, Atlanta, Ga. Other papers of interest will be presented.

Prof. Robert Battey, of Rome, Ga., has promised to be present.

This meeting will be held in response to the following call issued by a number of societies in Alabama, Georgia and Tennessee:

"The members of the medical profession in Alabama, Georgia and Tennessee are requested to meet in Chattanooga on the third Tuesday in October, for the purpose of forming a Tri-State Medical Association. All will be admitted to the meeting of the Association, but the membership will be restricted to graduates of regular medical colleges in good standing."

A Constitution will be adopted at this meeting which will regulate all matters pertaining to the society. The meeting will be called to order at 10 A.M. Tuesday, Oct. 15th, at the Chamber of Commerce. The sessions will continue two days.

FRANK TRESTER SMITH, M.D.,  
Secretary of Committee.

**IS LEPROSY HEREDITARY?**—ORTMANN (*Archiv f. Derm. und Syph.*) gives a concise abstract of a paper by Dr. Amauer Hansen, in which the author gives the result of an interesting investigation. He went to America to visit the lepers who had emigrated from Norway, and examined in the States of Wisconsin, Minnesota and Dakota lepers who had originally left Norway and their descendants born in America. He arrived at the interesting result that of 160 lepers who had emigrated to America, the offspring had remained free to the third generation. This result shows emphatically that leprosy is not a hereditary disease. The fact that, of the 160 emigrants, only sixteen or seventeen are still alive without any new case having sprung up does not, in his view, show that leprosy is not contagious. The different mode of life in the new country does not afford the same opportunity of contagion that is given by the peculiar conditions of life in Norway.

#### Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 21, 1889, to September 27, 1889.

By direction of the acting Secretary of War, Major Geo. M. Sternberg, Surgeon, having completed the duties assigned him in War Department order dated February 4, 1889, S. O. 30, February 5, A. G. O., is reassigned to duty as attending surgeon and examiner of recruits at Baltimore, Md. Par. 12, S. O. 218, A. G. O., September 19, 1889.

By direction of the Secretary of War, the station of Major Leonard Y. Loring, Surgeon, is changed from Ft. Mojave, Ariz. Ter., to Ft. Wingate, N. M., and he will report for duty at the latter accordingly. Par. 7, S. O. 219, A. G. O., September 20, 1889.

By direction of the Secretary of War, Capt. Henry G. Burton, Asst. Surgeon, will report in person, on the expiration of his present sick leave of absence, to the commanding officer, David's Island, New York for temporary duty at that station, and by letter to the Superintendent recruiting service. Par. 3, S. O. 223, A. G. O., Washington, September 25, 1889.

#### Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 28, 1889.

Medical Director A. C. Gorgas, detached from examining board and to hospital, Philadelphia, Pa.

Medical Director W. T. Hord, detached from hospital, Philadelphia, Pa., and wait orders.

Medical Inspector E. S. Bogert, detached from Newport Navy Yard and to examining board.

Surgeon D. McMurtrie, detached from U. S. S. "Vermont" and to Navy Yard, New York.

Surgeon H. J. Babin, ordered to the receiving ship "Vermont."

P. A. Surgeon C. H. H. Hall, resigned from the naval service, to take effect November 1, 1890, and resignation so accepted.

### THE MANAGEMENT OF INFANTS UNDER A YEAR OLD, HYGIENIC, DIETETIC AND MEDICINAL.

*Read in the Section of Diseases of Children at the Fiftieth Annual Meeting of the American Medical Association,  
June, 1889.*

BY T. B. GREENLEY, M.D.,  
OF WEST POINT, KY.

When we consider the great mortality of early childhood, compared to other periods of life, it induces inquiry on the part of sanitarians and clinicians as well as philanthropists to endeavor to ascertain why it is so. In this country the death-rate of infants under one year is 60 per cent. of all who die under five years.<sup>1</sup> This is a very astounding fact and greatly calculated to arouse the sympathy and interest of all good men.

We know that this great mortality cannot be due altogether to natural or unavoidable causes, and therefore it behooves all workers in the medical profession as well as philanthropists to investigate the causes and, to the best of their ability, mitigate as much as possible such a dire calamity.

The question may arise in the minds of some, why is it that the young of the inferior animals are not subject, to some extent, to disease and death, like our infants? Can it be that they take better care of their young; that they have better ventilation; that the mammifera afford a better milk supply; that they better protect them from violence? Is civilization one of the factors detrimental to infant life? Can it be that we, more than the brute creation, violate the laws of health and cleanliness to such an extent as to procreate weakly and diseased offspring?

In discussing the subject before us I shall very cursorily speak of (1) the mortality, (2) the hygiene of infancy, (3) the proper food for infants, and (4) allude to some of the diseases incidental to that period of life. There can be but little doubt that a large proportion of infantile mortality is due to improper food, or, more correctly speaking, the want of proper food and unsanitary surroundings. A very large percentage of the mortality of infants during the first year occurs

during the first month and greatly diminishes as age advances.

In France, out of 1,000,000 births over 29,000 die the first week, 22,000 the second week, and 22,000 in the sixteen days following, showing a mortality during the first month of 10.36. The annual rate of mortality among infants aged one month and under one year does not exceed 114.6 per 1,000, whereas among infants from birth to one year of age it is equal to 165.6.<sup>2</sup> In a supplement to the twenty-fifth report of the Registrar-General of England, 1838 to 1854, we find a table of annual rate of mortality, per cent., at each month under one year of age. During the first month 57 per cent. die; second month, 21.80 per cent.; third month, 15.70 per cent., and so on, rapidly decreasing as age increases. To those unfamiliar with such statistics this would seem astounding.

These statistics should remind us that there are causes producing such terrible mortality aside from disease. No doubt many children die in the first month from congenital causes due to disease of their parents; and, on the other hand, many die from neglect, starvation and exposure, and some from infanticide, while many die from the effects of improper food. Now, after considering the great mortality of infancy during the first year, the question is strongly presented to us, what can we do as sanitarians, philanthropists and medical men to modify or curtail it? Can we do anything? The solution to these questions consists mainly in endeavoring to ascertain the causes underlying such a terrible death-rate, and, to the best of our abilities, remove them.

We have already intimated that, to a great extent, improper food was a prominent factor in this respect, as well as exposure, neglect, starvation and infanticide. If we visit localities of the poor in large cities, where squalor, filth and degradation prevail over everything else in the way of cleanliness and good morals, we can to some extent account for the excessive death-rate of infants recorded in most of our large cities.

Now, what can be done to ameliorate the condition of the indigent poor who crowd the alleys and cellars of our cities? We are familiar, to a great extent, with the cause of a great deal of

<sup>1</sup> Vital statistics, U. S. census 1880.

<sup>2</sup> British Medical Journal, June 12, 1875.

poverty existing in such localities. I allude to the excessive use of alcoholic liquors. This is one cause we cannot remove outside of legislative enactments; for as long as politicians rule, spirituous liquors will be for sale, no difference what the consequences may be. But from a sanitary point of view a good deal might be accomplished in such localities. It should be the duty of the sanitary officers of cities to superintend the renovating and disinfecting of such unhealthy premises, and see that ventilation and cleanliness as far as possible are secured to the families of the poor.

As to the effects of inebriation, we have but little hope of amelioration; but when it is found that children are starving, neglected or abused in any way, they should be taken from their parents and placed in charitable institutions provided for their benefit. This part of the work of saving children would mainly fall to the lot of philanthropists. It has been said by some good people that it would be as well for mankind if the children of inebriates were all to die, so that we might soon be rid of drunkenness. This idea is expressed on the hypothesis that drunkenness is hereditary from parent to child. Regarding this as being true, of which there is little doubt, the proposition would not destroy the habit, as, unfortunately, many young men and boys acquire it from force of association and imitation. The idea may have originated from the theory of scientists that it would be in accordance with the law of survival of the fittest.

There is another cause in force which destroys the lives of many infants. I allude to syphilis. We have no idea of the great mortality resulting from this cause unless we examine the register of hospitals for infants. Most all children inheriting this disease die before they are a year old, and a large majority perish during the first two months. Now, can we do anything to diminish this mortuary record?

As a large majority of these children are born in cities, something, perhaps, might be done in the way of stamping out the disease. Several years ago the plan of licensing and inspection was tried in St. Louis, and it was said by Dr. Bernard, who was supervisor of inspection, that during its existence it curtailed the disease about 40 per cent. But the law was short-lived, as it was so repugnant to the minds of the religious element of the population that they soon rebelled against it, and it was abolished. They seemed to be actuated by the principle that, although it may be understood that moral disease exists among us, we must not acknowledge it openly. The St. Louis law was that every house of ill-repute was granted a license, and, on inspection, every inmate who was not diseased was granted a certificate of health, and those who were found to be diseased were refused a certificate. Now

the question arises, was there not an element in this law lacking, as far as it respects stamping out the disease? It should have been fuller in its provisions. Every woman found with the disease should have been put in a hospital for the treatment of syphilis.

It was the licensing part of the law that the religious part of the population complained of, which could have been left out. There is but little doubt that inspection comes the nearest of any means we possess, added to confinement in hospital until well, that promises to stamp out the disease or greatly limit its present extent. It may be said, in this regard, that many places of a private character would be overlooked, but by strict surveillance of proper officers all such houses of resort would finally be discovered. It is impossible to ignore the existence of such an evil. We have had it among us for centuries, and if it is the result of super-civilization, so much the worse for humanity. I think it must be evident to the minds of all observers that if syphilis and alcoholism could be eliminated from the world, the death-rate of the race would be wonderfully abridged; and if by any means possible such a utopian condition of the world could be brought about, the millenium would be near at hand and humanity would rise up as one man and pronounce the authors of such results the great benefactors of their race.

As for the filthy condition of the streets, as before remarked, where the poorer classes congregate, as well as the unventilated tenement houses are concerned, much could be done by the proper surveillance of the health officers. It must be patent to the observation, at least of all medical men, that it is in such localities where epidemic diseases find their greatest number of victims. The construction of tenement houses, as it regards drainage and ventilation, should be under the supervision of a health officer. All such things as these can be regulated by municipal authority. The women living in such unhealthy localities cannot be in good health themselves, and, consequently, their offspring will be affected thereby; and in many instances the infants, to start on, are independent of hereditary diseases, anæmic, or possessed with very feeble constitutions, added to these impoverished milk and unsanitary surroundings. These are common causes of mortality among infants. In such places as these we find overwork and the want of proper nourishing food on the part of the mother as the causes of bad health and death among infants; while in higher life, among fashionable women, other causes militate against infantile health and life. Here we find imprudence in dress, inactive life, late hours and irregular habits, producing impaired appetite and digestion, and, consequently, a poorly nourished embryo. And after birth the little impoverished waif, on account of the

fashionable tenets of the mother, is greatly neglected, perhaps committed to the care of a careless and incompetent nurse : and if the little thing dies it is recorded in the mortuary list as having died of inanition, when really it was from neglect and starvation.

Can anything be done that will work a favorable change in this particular? It is feared the world will be compelled to wait an indefinite time, at least until common sense and proper maternal instinct resume, to some extent, their ancient domain. Fortunately these unnatural habits and lack of philo-progenitiveness are confined, comparatively speaking, to but a small portion of our population. In order to make a comparison between the offspring of such parents and that of those who observe regular habits, take due amount of exercise and observe the proper maternal care of their infants, we have only to note the contrast presented between the two classes of children. If we go into the country we commonly see not only large families of children, but stout and healthy ones. Here their mothers, as a rule, observe the various means to preserve health, and furnish a healthy supply of nourishment to their offspring. Could not the profession who have charge of the fashionable portion of humanity as their clientage exert a salutary influence over them in this particular?

It is said by a late writer in this regard, that "it is a common thing to find in fashionable families but few children, hardly ever more than two to four at the highest, many having only one and a poodle dog, and some only the poodle." If they have been unfortunate enough to give birth to many children, death has claimed a majority of them through neglect, if not disease.

As the mortality of infants during the first month of life is so great, it behooves us to have special supervision over them. As far as possible a healthy, ventilated room should be chosen for the lying-in woman, the temperature of which should be kept equable at about 80° F. When the child is born it should be kept, if possible, in a temperature of 90° or 95° until it is washed and dressed, and then placed in bed alongside its mother. Many infants have perished from the effects of exposure between birth and being dressed. As soon as convenient the child should be allowed the breast, whether there is milk present or not, so that it may learn to nurse. Of course, if the breast contains no milk, which is common until the second day, the child must be fed on fresh cow's milk. After the secretion of milk is established the infant should be allowed the breast every four or five hours, or oftener if necessary. The mother should avoid taking any drugs in sufficient quantity to affect the child deleteriously. The position of the child should be changed frequently, not allowing it to remain in one position more than a few hours at a time,

say when it nurses or is fed. This is essential on account of the bones of the head not being sufficiently compact to support the gravity of the brain so as to preserve its proper shape. Many children, from inattention in this particular, have misshapen heads. When children are born in cold or changeable weather they should wear caps. Neglect in this regard frequently eventuates in cold in the head, producing discharges from the nose and ears, which not infrequently becomes chronic. An infant should not be washed all over in cold weather oftener than once a week, and then always in a temperature not less than 80° or 85° and with warm water. Care should always be observed that the flexions of the joints and the folds of skin around the neck are dusted daily with some finely prepared powder to prevent chafing, the finely prepared chalk being as good as any. An infant should not be taken out in cold weather unless well protected with heavy, warm clothing and well wrapped up. Young children are very easily impressed with cold from exposure, and on that account more liable to inflammations of the chest, brain, etc., than older children. Special supervision should be exercised over them in this particular. Close attention should be exercised over the digestive apparatus of infants, and particularly so in their early life, when deprived of the mother's milk. As a rule, a child under its mother's care, when she is in good health, needs but little outside attention; but when it is necessary to feed it on artificial food it is liable to indigestion, flatulency, colic, etc., which, if not corrected, will soon prostrate it. This is more particularly so in hot weather. This condition, in many instances, is due to the use of milk undergoing fermentation, and to neglect in properly cleansing the nursing bottle, etc. In warm weather it would be better to obtain fresh milk from the cow three times a day, and every time a bottle is used it should be thoroughly cleansed and rinsed with a warm solution of common soda and allowed to remain in the sunshine until needed for further use. A young infant fed on cow's milk should have the bottle every three or four hours, so that it will not, by becoming very hungry, take too much at a time and thereby engender indigestion and colic by over-distension of the stomach.

It is a question among the best men in the profession whether or not cow's milk should be diluted. A majority of those writing on the subject recommend dilution from one-fourth to three-fourths, according to the age of the child. As far as my observation extends, I prefer to use the milk undiluted. When we dilute cow's milk to one-fourth it requires a large quantity of it to furnish a due amount of nourishment, which, if the child takes enough, so distends the stomach as to produce colic, and if kept up sufficiently long we will have disordered digestion, diarrhœa

and colic, due to over-distension of the organ. And, on the other hand, if a sufficient amount is not taken to produce over-distension of the organ, gradual starvation will ensue.

When I promised our worthy Chairman to write this paper I consulted my friend Prof. Howe, scientist of the Louisville Polytechnic Society, in regard to milk, etc., as food for infants, the reagents necessary for digestion, etc. He kindly furnished me the following notes:

*First.*—The food which nature has provided for the infant is presumably the best. This consists essentially of

1. Casein—the nitrogenous food, flesh-former.
2. Sugar the carbonaceous foods, heat and
3. Fat force producers.
4. Salts—bone former.
5. Water.

*Second.*—In all foods prepared for infants the latter ingredients are present in sufficient quantity, and play not a small part either in starving the infant or impairing its power of digestion.

*Third.*—Casein. The casein of woman's milk is characterized by not forming a solid curd when acidified. This, among the mammalia, is said to be true only of the milk of woman and the mare. Other milks form more or less tough coagulum when acidified, and hence the infant's stomach at once assumes a condition in which the feeble digestive fluids of the infant fail to act upon them. On the other hand the casein of the milk of woman or the mare in the infant's stomach is so finely divided that it is digestible. This is a plausible reason why infants have been found to thrive better upon mare's milk than upon that of cows (carried out on a large scale in Paris), even though the proportion of its ingredients is not that of woman's milk. It has been attempted to obviate this difficulty of coagulation by diluting cow's milk (ineffectual), or by adding various farinaceous materials which are in themselves indigestible by the infant, as mentioned later.

This difficulty may be obviated by partially digesting cow's milk (peptonizing, a process which requires some considerable care), or by malting, both of which seem to render the casein of cow's milk digestible by the infant.

*Fourth.*—Sugar. Nature has provided for the child an animal sugar—lactose, or milk sugar, which is distinguished from all vegetable sugars by yielding, upon fermentation, lactic acid, an acid which in itself plays an important part in digestion. Milk sugar cannot safely be substituted in an infant's food by any vegetable sugar, such as cane or grape sugar, both of which are very readily fermentable and produce alcohol and acetic acid.

*Fifth.*—Much less can the sugar be substituted by starch in any of its forms, nor can any form of starch be safely used in an infant's food, as is most commonly done in most so-called infants'

foods. Nature has prepared *animal* food for the infant; no *vegetable* food can be a substitute.

As regards starch, the infant's saliva contains no ptyalin, which is important for its digestion, and in many cases at least the various starch preparations will pass through the infant's digestive canal in a wholly undigested condition, and the infant, eating heartily, may be hungry all the time and finally starve to death.

We are frequently asked by parents if it is not better to feed infants on other food besides breast milk. The answer should be infallibly no, unless the mother gives an insufficient supply. It is shown by Dr. Whitehead's tables that the children fed on breast milk exclusively resulted in perfect development in 67 per cent., medium development in 23 per cent., and bad development in 14 per cent.; whereas in children fed partly on breast milk and partly on other food there was good development in only 52 per cent., medium in 19, and bad in 39 per cent.; and lastly, as opposed to these results, where hand feeding was used entirely, there was good development in 10 per cent., medium in 26, and bad development in 64 per cent.

If an infant is so unfortunate as to be deprived of its natural food, either on account of the heartlessness of its mother or some accidental cause, it should be committed to the care of a competent, careful nurse. In selecting a nurse it is essential that one of good moral character should be chosen, and, if a wet-nurse, that she is perfectly healthy. Even if one of this character is selected she and the child should be under the supervision of the medical attendant at least once a week for several months, in order to know that the child is well supplied, that it digests its food, and that it is well taken care of.

I believe more infants die from neglect, exposure and want of proper food than from actual disease, aside from heredity. Then, if these matters could be properly supervised, there would be a great saving of infantile life. Many times, if the nurse is of a vicious and reckless disposition and the child becomes fretful from indigestion, hunger or pain, it is dosed with some opiate preparation, or perhaps alcoholic beverage, in order to quiet it and thereby secure time for her own benefit. Habits of this kind practiced on infants are very injurious to health, tending very greatly to impair the digestive functions and vitiate the secretions, to say nothing of ultimate injurious effects that may result.

I have always thought that a mother in good or ordinary health, who, for the sake of enjoying fashionable life or for any other selfish motive, would commit her child to the *tender mercies* of a wet-nurse, or, in fact, any other, is destitute of that natural instinct which pertains even to all inferior animals, and that she, in so doing, not only commits a sin against true motherhood, but

is guilty of possible, unintentional infanticide. Children under a year old, as a rule, when fed on breast milk, need but little medication, unless affected by contagious diseases peculiar to them. To be sure, in cities, during the hot season, we may have some bowel affections which are, apparently, unavoidable. It would be well, in extremely hot weather, to take delicate, and especially bottle-fed, children to the country, where a change of air would do more good than medicine. But on account of want of means a large majority of city children are deprived of the advantage of such a change. It is under circumstances of this kind, particularly in unsanitary localities, that hot weather diseases run up such long mortality lists. This character of children's ailments make up a large ratio of the death-rate in cities during the hot months. I have thought that, through charitable organizations, aided by municipal authority, homes for indigent children might be constructed, where they could be cared for during the summer months and thereby save the lives of thousands who otherwise die from neglect, the want of proper nourishment and from unsanitary surroundings. Much good could be accomplished during extreme hot weather in such buildings by the use of large fans in the various rooms, kept in motion. The difference between hot air in motion and in a state of rest becomes very palpable when we go from a close room into the open air, where there is a breeze. Although the temperature is the same, warm air in motion produces a cooling and an invigorating effect. How grateful it is even to be fanned in the face when one is almost overcome with heat. Large fans could be easily and cheaply constructed and worked at an inconsiderable expense. Netting, something in the form of hammocks, could also be arranged in the rooms to serve in the place of beds for the children, which would allow the animal heat to escape much more readily than from ordinary beds. The netting should be so arranged as to be as nearly horizontal as possible. This would be a very eligible and beneficial arrangement, more particularly in cases of disease accompanied with very high temperature.

Infants, as before remarked, under ordinary circumstances need but little medicine, and that of a mild character. It has been a habit with me for years to use the most simple means in children under a year old. Colic and disordered bowels due to indigestion are the main troubles we are called upon to treat during the first months of infant life. If the child is fretful and restless, with tympany of the stomach, a little ginger or mint tea, sweetened, will in a majority of cases afford relief. Should there be much pain, add a few drops of paregoric. When this is due to indigestion, a little lactopeptine and bismuth sub. nit. might be given with advantage after each nursing.

In cases of diarrhoea accompanied with acidity of the discharges, which is generally evidenced by the smell as well as a foamy appearance, the first thing to do is to correct the acidity. For this purpose a little sublimated or prepared chalk is about as good as anything. This alone will frequently correct the condition of the bowels; but should an astringent be needed, a little syrup made of the fluid extract of cranesbill is as effective and simple as anything we can use; but do not attempt to arrest diarrhoea due to acidity and fermentation by the use of astringents alone. Many times, after the acidity has been corrected, the diarrhoea can be arrested by minute doses of castor oil, say a drop or two given every fifteen minutes until it passes the alimentary canal. The same thing may be accomplished by very minute doses of calomel, say  $\frac{1}{10}$  of a grain every half hour until its effects are observed in the discharges.

In an attack of cholera infantum the child should, if in the city, be removed to the country or some place where it can have pure air and healthy surroundings. More, as a rule, can be done by sanitary means than by medicine. If the diarrhoea is accompanied by acid vomiting, administer fresh milk and lime water in small doses frequently repeated, and as soon as the vomiting has ceased exhibit minute portions of calomel or hyd. cum creta frequently repeated until the character of the discharges is changed and become more consistent and less frequent. I have also had good luck in the use of subnitrate of bismuth and Dover's powder in the treatment of cholera infantum. Food should be withheld from the infant during the existence of the acute symptoms. Should the case be protracted after the acute stage has subsided, it would be well to use cretaceous preparations with astringents, such as acetate of lead, cranesbill, kino, etc.

In chronic constipation of young babies harsh purgatives must be avoided, as well as hydrogogues. I have had good results from syrup of figs, cascara sagrada, rhubarb, etc.; but if the child is debilitated combine some muscular tonic, as tinct. nux vom., columbo, etc.

In the various contagious diseases of children isolation is an important element in their management.

In writing this paper it was not intended to claim any superiority over my confrères in the management of infantile life, or with the expectation of presenting anything new in the way of treatment, but more particularly to impress them with the necessity of a closer supervision over young children, more especially during the first months. If, by our attention and advice to parents, we can tide a child over the first year, its prospects to live ten years are increased 50 per cent. It therefore behooves the medical man, as well as parents and nurses, to exercise careful

supervision over their health during that period. If each one of us could, by increased watchfulness, save even one additional life annually over what we have accomplished in the past, it would add greatly to the population of our country.

DR. SEARS, of Texas, said that the life of a child depends very much upon the care it receives during the first months of its existence. There was great ignorance among the people generally as to the quantity of food a child should have, its nature, and the time and manner of feeding. Infants were, as a rule, too frequently nursed.

DR. WHITNEY, of Rhode Island, thought the author had overstated the prevalence of syphilis in children—for New England, at least. He would especially call attention to straining as a cause of infantile hernia. He had never seen a case of true congenital hernia. The condition at birth is simply *favorable* to the production of hernia and for its production.

DR. WILLIAM PERRY WATSON, of New Jersey, took exception to the advice given by the author of the paper in regard to wearing a cap. He directs mothers to keep the heads and necks of their infants bare, and by this means inures the children to temperature changes. As a result he has very few cases of nasal and pharyngeal catarrh among his practice.

DR. LATIMER, of Maryland, said that for artificial feeding there was no testimony defending anything but cow's milk. The doctor called attention to the differences between cow's and human milk, and said that Dr. Meig's method of preparation was to be highly commended. Nothing had been said in the paper about sterilized milk. The mother's milk was taken by the infant directly from the breast and was practically sterile, no opportunity being given in its passage from the mammary gland to the child's stomach for infection with the spores of decomposition microbes. During the hot months the infection of milk with decomposition microbes was a most important factor in the production of infantile diarrhoea, and the sterilization of the food was a necessary prophylactic measure.

## THE PURIFICATION OF DRINKING WATER FOR CITIES.

*Read in the Section of State Medicine, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY CHARLES V. CHAPIN, M.D.,  
OF PROVIDENCE, R. I.

The importance of the purification of public water supplies was impressed upon the writer with special emphasis by the brief epidemic of typhoid fever which occurred in Providence last fall. At that time there occurred in the space of two weeks about 250 cases and forty-seven deaths. The

cause of the outbreak was the contamination of the river which furnishes our water supply, by the stools of typhoid fever patients. That similar occurrences are by no means rare is well known, and probably instances of the kind have come under the personal observation of very many of the gentlemen here present.

The impurities which are liable to be found in the public water supplies of cities are varied. There may be coloring matter from swamps and bogs or other sources which renders the water disagreeable to the sight. The water may be muddy from the presence of clay or earth. It may contain infusoria or algæ which, of themselves or by their death and decomposition, may render the water exceedingly unpleasant both to smell and taste. The water may also contain larger organisms, such as the eggs of worms, parasitic or otherwise, molluscs or fish, particularly eels. Lastly, the water may contain the active virus of disease. While the other impurities in water which have been mentioned may often be sufficient to demand active measures for their removal, it is the actual pathogenic properties of water which are of peculiar interest to medical men. The disease which far more often than any other has been traced to water is typhoid fever. Medical literature is full of instances where epidemics of greater or less severity have been unquestionably traced to a public water supply. Cholera is another disease which has often been distributed by the same agency. Besides these two in which the facts are beyond dispute there is some evidence to show that dysentery, diarrhoeal diseases and malaria may occasionally gain access to the human system through the medium of drinking-water. Now, it has been determined that typhoid fever, cholera and malaria are caused by minute living organisms, and it is most likely that the other diseases mentioned are caused by similar organisms. Hence if we desire to deprive water of its pathogenic properties, and that is the problem which I now wish to consider, we must determine how these organisms can be removed or kept out of our public water supplies. It is true that these organisms doubtless act on the body by means of the soluble chemical products of their vital activity. But such substances can never exist in any potable water in quantity sufficient to do harm, so that if we can remove the organisms themselves we can rest assured that the problem will have been solved.

There are three points at which contamination may be dealt with:

The first is at the source, be it river, lake, spring or well. Every gentleman here will agree with me that no municipality should spare any expense or neglect any legal expedient whereby dangerous contamination of the source of its water supply may be avoided. In many instances, by suitable means of control the water may

thus be kept substantially pure. But in other cases, when the source is in a thickly settled region, this is practically impossible, and fatal contamination is at any time liable to occur. This is well illustrated in the Providence epidemic referred to. Our source of supply is a river flowing through manufacturing villages. At the point where the infection took place the owners of the mill tenements had provided water-tight vaults at a suitable distance from the river, and frequent inspections were made by the Board of Public Works to see that they were kept in repair. But when typhoid fever occurred in these houses the tenants, instead of using the vaults, threw the stools on to the bank of the stream, whence they were washed into the water by the heavy rains.

A second point at which the water supply may be purified is at the point of consumption. To accomplish the removal of the germs of disease as well as of other suspended particles, domestic filters have been used. Sometimes they remove the dirt, sometimes they do not. In any event they do not remove the living bacteria. The experiments of Dr. Swarts, of Providence, show that with one exception the domestic filters offered to the public in this country are worse than useless because, instead of removing microbes from the water, they rather serve as incubators to increase their number. The only filter which he found could be relied on to furnish germ-proof water was the Pasteur, but its cost puts it beyond the reach of all but the wealthy. Boiling water of course destroys all organisms, but it will never be resorted to by the majority of consumers.

Lastly, we must consider the treatment of the whole supply centrally by the municipality. A large amount of experimental work has been done in relation to the removal of microorganisms by filtration through sand or other media, one of the pioneers in this direction being Prof. Pumptelly of this city. Such work has also been done by Hesse and Piecke in Germany and by Frankland in England. But the most recent and elaborate, and particularly interesting from a bacteriological point of view, is the work in filtration which is now being done by the State Board of Health of Massachusetts. These latter experiments are performed chiefly with sewage, but the results attained throw much light on the filtration of potable waters.

The conclusions which have been arrived at are that for continuous filtration on a large scale fine, sharp sand is the best material. The finer the sand the better is the removal of organisms and other suspended matter accomplished, but the slower is the filtration. A rate of from 1 to 2 gal. per sq. ft. per hour has been found to be the most available for practical work. The thickness of the sand makes some difference, but not as much as might be expected, for the upper layers exert by far the greatest influence in removing the organisms.

Strange as it may seem, fresh sand is not as effectual as that which has been in use some time, and sterilized sand has the least value of any. This is explained on the supposition that the grains of sand when in use soon become encrusted with organic matter which serves to entangle bacteria and other solid particles. The heating during sterilization destroys this. It is certainly possible by means of sand filtration to remove all bacteria from water. In one of the filters tested by the Massachusetts State Board of Health the organisms in the applied sewage were reduced by filtration from over a million to less than a score, and sometimes none at all were found. In fact, it was demonstrated that the few organisms discovered in the effluent were only such as inhabited the effluent pipe. When enormous numbers of known forms were poured on to the top of the filter none at all could be discovered in the effluent by repeated tests. The depth of sand in this filter is 5 feet and the rate of filtration is very slow, 1 gal. per sq. ft. per twenty-four hours. While this filter purifies the sewage so that it can be and is used for drinking purposes, it is far too slow for actual practice.

Passing from this experimental work we will now briefly consider some of the filters which are in use for supplying drinking-water to towns.

Of filters on a large scale for potable water those at Berlin were the first whose workings were investigated from a bacteriological standpoint. Ever since 1884 regular weekly chemical and biological analyses have been made of the water both immediately before and after filtration and as delivered at the house taps. These experiments, conducted at the Imperial Bureau of Health, furnish the most complete and valuable data concerning the action of this class of filters. Berlin draws its water from two sources, the rivers Spree and Havel. The former is much polluted and contains a large number of microbes, sometimes as many as 100,000 per cc. The Havel supply has a smaller number. The water from both sources is passed through sand filters. The total area of these filters is about 67,000 gm., or nearly twenty acres. They consist of masonry basins containing successive layers of stone, gravel and sand, the essential portion being the upper layer, which is of fine sharp sand and is about 22 inches in thickness. The manner of using the filter is of particular interest, for it is upon this that its value has been found to depend. It is first slowly filled from below with filtered water so as to drive out the air. Unfiltered water is then admitted from above until it is 1 m. in depth above the surface of the sand. It is then allowed to stand until the suspended matter is precipitated upon the surface of the sand in the form of a delicate film. This is an essential feature, for it is this superficial layer of sediment which gives the apparatus its value as a filter. The effluent valves are now

slowly opened and filtration begins. The rate of filtration is at the maximum about 3 cm. per twenty-four hours through each gm. of surface, or a little less than 1 gal. per hour per sq. ft. The amount, however, rapidly becomes less, and it becomes necessary to clean the filters every four to ten days according to the amount of impurities in the water. The cleansing is done by drawing off the water and removing by means of flat shovels a very thin layer from the upper surface of the filter, for it has been found that the impurities do not penetrate more than a few millimetres. The chemical analysis shows that by this filtration all of the free ammonia, very small in amount, and a large percentage of the oxidizable material (oxidizable by potassic permanganate), and a considerable amount of the volatile residue is removed.

As regards the removal of bacteria, the weekly examinations of the unfiltered Spree water for the year ending June, 1886, gave the average number of organisms per cc. as 11,278, while in the water immediately after leaving the filter bed there were but 179. The unfiltered Havel water contained 2,628 and the filtered 97. In the former case about 98.5 per cent. and in the latter about 96 per cent. of the microbes were removed. The larger organisms, the algæ and infusoria, are completely removed. It is said, however, that the spores of these algæ do to some extent pass through the filter, so that if the water is stored in reservoirs after filtration algæ sometimes develop there in great quantity. That not only good construction but great care in the management of this class of filters is necessary is illustrated by the fact that Currier found that an American filter constructed on the Berlin plan allowed more than half the organisms to pass through simply because it was not properly cared for.

For many years the various water companies supplying the city of London have employed sand filtration to improve the quality of the water furnished by them. Their filter beds are constructed on substantially the same principle as the Berlin beds, and consist of a layer of fine sand supported on coarser sand and gravel. The thickness of this sand varies from  $2\frac{1}{2}$  to  $4\frac{1}{2}$  feet. The rate of filtration is from 1.5 to 2 gal. per hour per sq. ft., which is considerably more rapid than in the Berlin filters, though the thickness of the sand is greater. These filters are cleaned at varying intervals depending on the amount of sediment in the water, the usual time being once in two or three weeks. The action of these filters in removing microbes from the water was investigated by Percy F. Frankland, who found that the average number of organisms removed from the water was 97.7 per cent. for the Thames companies and 95.7 per cent. for the Lea companies. In some instances, however, as many as 99.4 per cent. were removed. The number of organisms in the unfiltered Thames water varied from 4,800 to 45,000,

and in the Lea water from 2,900 to 39,000. In one instance the filter of the New River Co. reduced the organisms from 20,600 to 74. It is estimated by practical hydraulic engineers that in this country the cost of filter beds of this character would be \$25,000 per million gal. of supply, and that the running expenses and interest on plant would bring up the cost of filtering to \$10 or \$11 per million gallons of water filtered.

Of late years a number of patented filters have been put on the market by American makers and are now in use in many manufactories and in conjunction with several town supplies. In this form of apparatus the water is filtered under a considerable pressure, 40 lbs. or more, and the rate is very rapid and the filters themselves occupy a very much smaller amount of space than do the European gravity filters.

The Hyatt filter consists substantially of a circular wrought iron tank containing as a filtering material about  $4\frac{1}{2}$  ft. of moderately fine sharp sand, with about 18 in. of coke (locomotive cinders) on top. This latter is for the purpose of catching the suspended organic matter and preventing its choking the sand. The water passes through the filter under pressure. The resistance of the filter is about 3 lbs.; that is, it decreases the pressure of the water passing through it to that extent. At proper intervals, usually once every twenty-four hours, the filter is cleansed by sending a reversed flow of filtered water up through it, violently agitating it and washing out all the precipitated material that has been removed from the water. The washing takes say ten minutes, and the filter is then ready for use. There is said to be practically no loss of filtering material and it never needs renewal. The rate of filtration is about 125 gal. per sq. ft. per hour. An essential part of the claim of the owners of this filter and of the others which resemble it, is the employment of continuous coagulation with the process of filtration. This coagulation is accomplished by adding to the water before it enters the filter, by means of a suitable contrivance, a small proportion of alum or sulphate of alumina. The amount is easily regulated and the persons in charge of the filters allow a sufficient amount to enter to ensure an effluent which is satisfactory on gross examination. The actual amount used in the filters of this company is said to vary from  $\frac{1}{16}$  to 1 gr. per gal., the average being  $\frac{1}{16}$  gr. An important question is what becomes of this alum? Prof. Chandler states that he took samples of the water of the Raritan River before and after filtration by the Hyatt filter, which is in use at the Somerville waterworks. He found alum present in the unfiltered water in about the amount in which the operators of the filter claimed they were adding it— $\frac{1}{16}$  gr. per gal. The water after filtration he found "did not contain a trace of alum." Other analysts have obtained the same results. It is

claimed by the makers of these filters that the alum all unites with the organic matter in solution in the water and, forming a part of the coagulum, is removed with it. Whether this is true in all instances I am not prepared to say, enough experiments under varying circumstances have not as yet been made to determine it with certainty. We can be sure, however, on general principles, that a considerable amount of alum must be decomposed and removed in this way if there is much organic matter in the water, and the alum would not be added unless this organic matter were present. In the localities where this process is in use there is no complaint of any taste of alum in the water, nor any complaint that I have heard of from medical men that the added alum causes any digestive troubles. And we should hardly expect that it would, for even 1 gr. in a gallon is an extremely small amount, and much less than this is the usual quantity employed and a large part of this must be removed in the precipitate. On studying alum baking powders Prof. Mallet found that 20 gr. of alumina hydrate were required to affect digestion unpleasantly, and it is hardly to be supposed that the amount derived from even  $\frac{1}{3}$  gr. taken in twenty-four hours in divided doses would produce any bad results. And  $\frac{1}{3}$  gr. is as much as would ever be taken by one person even if it all passed through the filter. It seems highly improbable, then, that the addition of alum to potable water to produce coagulation preparatory to filtration can produce any injurious consequences on the consumers.

The National filter is another filter of this class which has come into quite general use, and which differs from the Hyatt in what are apparently minor points. The makers of this filter recommend that when it is used to furnish a town supply a pump be used to add the alum solution, thus ensuring a more certain regulation of the amount than can be obtained by the regulation which depends on a supposed constant rate of solution.

The waterworks in this city have recently put in a filter which will be described to you by Dr. Rankin, and which seems to differ from the Hyatt only that it is open to the air and filters under a head of a few feet only, and is so very much larger that the rate of filtration is hardly one-fifth as great as in the Hyatt and National filters. These points of difference seem to be in favor of the Newport filter, and why it does not give better results I cannot say. The owners, however, do not claim that it is yet in proper working order, and have certain changes to make which they expect will improve it.

There are several other makers of this class of filters, but the Hyatt and National are the best known and seem to be good types of the principle of coagulation and continuous filtration under pressure.

For the purpose of examining the Hyatt filter

in person I recently visited Long Branch, where a 2,000,000 gal. plant was established a year ago. I found the plant in operation as described, and it had given great satisfaction to the users of the water ever since it had been put in. At the time of my visit the unfiltered water was of a dark yellowish brown color and had considerable organic matter in suspension. It was surface water from swamps and shallow ponds. The effluent was perfectly clear and colorless. The pumps were lifting at the rate of about 1,800,000 gal. per twenty-four hours, and the engineer was adding about 180 lbs. of alum during the same time. This would be a little less than  $\frac{1}{16}$  gr. per gal. The filters had been cleaned in the morning and I made a biological examination of the water in the afternoon. Three gelatin culture tests were made on the spot at intervals of half an hour. After a growth of thirty-six hours, at which time the liquefying cultures began to run together, the results were as follows:

	1st Test.	2nd Test.	3rd Test.
Unfiltered . . . . .	258	298	248
Filtered. . . . .	5	2	3

The only other biological test that I know of, of this filter, was a single one of Prof. Formad at Allegheny City, in which about two-thirds of the organisms were removed.

None of the National filters for town use have been accessible to me, but the makers of the filter suggested that a satisfactory test could be made at the Valley worsted mills, Providence, or at the bleachery at Canton, Mass. In the former place I found the alum was not used, and the filter was made to work under much greater pressure than was intended. It furnished water clear enough for manufacturing purposes, but scarcely half the microorganisms were removed. At Canton the alum was in use, and too much so, for it was stated by the engineer that he thought that  $1\frac{1}{2}$  grains per gallon was added to the water. What the amount really was I do not know, but it could be readily tasted in the effluent. Five tests gave an average of 86 per cent. of the organisms removed. Dr. Currier tested one of these filters at Brooklyn, and found that it removed a much larger per cent., and in one instance the effluent was entirely sterile. He also failed to detect any alum in the water.

The Newport filter I found had no appreciable effect in removing the bacteria from the water, and you have probably noticed that it leaves much of the other suspended matter. But as I am informed by Dr. Rankin, the amount of alum added is so small, and it is so largely removed by the filter that it can exert no injurious effect upon the water.

There seems to be then little doubt that both the sand filters in use in Europe and certain of the coagulating filters made in this country can

be relied upon to remove from 90 to 100 per cent. of the organisms contained in the water.

They cannot be relied upon to render infected water absolutely safe. But we know that the smaller the number of pathogenic organisms which a person receives the less liable is he to be affected by them. If nine-tenths of the organisms can be removed, I believe it is not far from the truth to assume that nine-tenths of the danger will be removed.

The cost of the European system is, as has been stated, \$10 per 1,000,000 gallons. The cost of the coagulating system is not more than half that. It is also, when properly constructed, much easier to manage. Its only disadvantage is in the addition of a foreign substance as a coagulant, and I am inclined to believe that further investigation will show that no danger is to be apprehended on that score.

Aeration has been spoken of and used as a means of purifying water, but it can only accomplish this to a very limited degree. There is no reason to believe that aeration has any influence on the growth of bacteria, and recent investigations have shown that its power of oxidation is very slight indeed. It is true that aeration is sometimes very useful in removing the smell or taste of water, but it accomplishes this by volatilizing or driving out the offensive substances, rather than actually oxidizing them *in situ*. At least this is the view now generally adopted by the best chemists.

There is another means of improving the water supply, at least, so far as bacteria are concerned, and that is by allowing it to stand in storage reservoirs. The experiments of Wölffhügel, Bolton, Frankland, and others, have demonstrated that pathogenic organisms, such as cholera, typhoid and anthrax bacilli and various pus-forming organisms soon die in ordinary river or well water, the typhoid bacillus living only about two weeks. Certain harmless aquatic forms do, however, live and propagate, but observations show that most of the bacteria found in our town supplies rapidly perish. This was found to be true at Berlin, and Prof. Sedgwick determined it for Boston. In Providence we have two reservoirs, both in constant use. One holding ten days' supply, the other three months. Bi-monthly analysis for a year showed as the average number of organisms in the river 354, in the ten days' reservoir 223, in the three months' reservoir 42. Storage reservoirs may, however, develop algae which, besides rendering the water unpleasant to the taste and smell by their death, furnish pabulum for the bacteria. But the growth of the algae can be prevented by covering the reservoirs, and it is not to be apprehended in every case.

In order to purify water then,

1. The source must be made as pure as possible.

2. Storage reservoirs should be built.
3. The water should be filtered by the municipality.
4. The consumer must boil the water if any danger is suspected to exist; but it is not likely to if the first three conditions are complied with.

DR. SMART took exception to the suggested idea that if nine-tenths of the bacteria are removed by filtration the danger is proportionately lessened. He said it was all very proper to filter water if the water was made purer by the filtration, and it was a good thing to have experimenters determine for us in such cases the extent of the purification that was effected; but he suggested that certain experiments had been performed to which no reference had been made by the author of the paper just read. Biological experiments, in which the organism had been cultivated, not on gelatine plates, but in the human system. The paper had a special reference to typhoid fever, and we all know of the propagation of typhoid by waters, well waters which had been filtered through the soil until they had lost all trace of their organic matter, and became apparently so pure that the chemical analysts were obliged to confess their inability in certain cases to say whether a water was wholesome, although it seemed to be pure. On account of this consideration he objected to placing any reliance on filtration where the contention was against typhoid fever. Water which has not been contaminated should be obtained from a community rather than permit its lives to be wasted by a fever germ which cannot be removed by filtration. Non-contaminated water should be procured, no matter what the financial consideration.

## EVISCERATION.

*Read in the Section of Ophthalmology, at the Fiftieth Annual Meeting of the American Medical Association, June 1897.*

BY A. E. PRINCE, M.D.,  
OF JACKSONVILLE, ILL.

It will be five years in September since Prof. Alf. Graefe, of Halle, delivered his address before the Society of Naturalists and Physicians at Magdeburg in which he described the operation of exenteration or evisceration, and asserted the advantages that it possessed (except in malignant diseases) over enucleation, viz.: that the danger of meningitis was avoided, and that a superior stump was thereby obtained. Besides the denial of these claims, by some it has been objected that the greater degree of pain, and increased amount of inflammatory reaction, together with the prolonged period of healing, were decided disadvantages to be taken into account.

It is not my purpose in this paper to review the arguments of the author regarding the advantages of the method; but first, to offer a consideration

relating to the chief objection, that of the consequent pain; and second, to mention an observation which may prove of value in securing a further improvement in the character of the stump.

#### PAIN.

All the published accounts of the operation which have come to my notice agree in the acknowledgment, that the severity of the pain and the duration of the healing is materially greater after evisceration than is the case following enucleation. My observation in the first five cases was a corroboration of these statements. The swelling was intense and the pain for several days was very great. Local application failed to afford relief, and morphia was required. At this period in my experience, stimulated by this discouraging feature, an effort was made to determine the cause of the pain. The anatomical fact that the long ciliary nerves lie in exposed grooves along the concave surface of the sclera, leading forward to the ciliary region, led at once to the hypothesis that the cause of the pain was the tension, pressure and inflammatory irritation to which these nerves were subjected.

To test the truth of this hypothesis the entire concave surface of the sclera was cauterized with pure carbolic acid immediately following evisceration in a case of extremely painful panophthalmitis consequent upon an incision, the suffering attending which had been intense for several days.

The result surpassed all expectations. The pain ceased with the operation. The degree of swelling was small and the patient was discharged in five days. Since this operation the number of eviscerations has been about twenty-five. The results have not been uniformly so brilliant. Sometimes the conjunctiva has become cedematous and been forced out through the palpebral aperture, but in no case, in which the cauterization has been efficient, has there been the type of pain which was remarked previous to the cauterizing treatment.

It is believed that the use of the acid in this connection is indicated

1. On account of its quality as an antiseptic.
2. Because it is an anæsthetic.
3. Because it is believed to close the apertures in the sclera, and thus prevent the escape into the orbit or sheath of the nerve, of any microorganisms which should escape the action of the acid.
4. Because the sensory nerves thus treated cannot respond in sensations of pain to the subsequent irritation and tension to which they are liable to be subjected.

#### STUMP.

The second question raised by critics is that of the nature of the stump.

That the question is one which deserves attention will not be denied. The inadequacy of the stump following enucleation needs only to be

mentioned. Dr. Mules, of Manchester, England, struck a responsive sentiment when he published his observation on the use of the glass vitreous, in 1884.

The general feeling was that it would be a great step forward in cosmetic surgery if his method could stand the test of experience.

From the little that has since been said of it I am led to infer that the practice, which was at first so extensively resorted to in Manchester, has not met with extended favor. My experience in the use of the artificial vitreous in six cases was at first very encouraging, but later equally discouraging.

While the balls were at the commencement retained kindly and the patient seemed overjoyed at the excellence of the stump, this joy was converted later into grief in five cases of the six by the absorption of the line of union and the escape of the glass ball. Though my experience in attempting to secure the permanent retention of artificial vitreous is to be regarded as a failure, yet there was an element of instruction in it which I offer for your consideration. It was noticed in some of these cases that even though the glass ball was retained but a few days, it left upon its escape a distended sclerotic, infiltrated with formative material which prevented the usual collapse, and enclosed a cavity which gradually filled with granulations and finally resulted in a stump which was fuller and more mobile than that following enucleation. Following the lead of this inquiry I was led from theoretical considerations, after cauterizing with carbolic acid, *to pack the cavity of the eviscerated globe with pulverized iodoform.*

The method which has been employed is to dry out the globe and, after pouring from a paper funnel into the cavity of the globe as much of the powder as it will contain, to tamp it with cotton on a cotton holder, making room for more of the iodoform, which also is to be lightly packed into the cavity. If packed too tightly the escape of the serum is impeded, and in that event, either forced to infiltrate into the orbit or extrude the plug of iodoform. Pursuing this process it has been observed in more than a dozen cases that the sclera remains partly distended by the iodoform, which may remain in position for several days or even weeks, in some cases.

In one case of recent injury in which I eviscerated, cauterized and packed with iodoform, on the following day no pain had been experienced and exceptionally no swelling had resulted. The patient was to notify me if he had any trouble. On the fifth day my assistant called and found that he had removed the bandage and taken a trip into the country. He subsequently objected to having the bandage reapplied, and was digging wells in another week. In his case a small plug of iodoform remained for three weeks and was finally crowded out by the encroaching granulations.

An excellent stump possessing good excursion was the result. After three months, considerable shrinkage has occurred, but there is still a fair degree of prominence and good motion. In no case in which iodoform has been packed into the sclerotic cavity has there been the least suppuration, which, to my mind, establishes the position of iodoform as an antiseptic, when it can be retained in contact with moist organized tissue, in the presence of which iodine is probably liberated.

The conclusion drawn from my experience is that, though the subsequent shrinkage is more than we would wish, yet, the resulting stump is sufficiently better than that following enucleation to lead me to prefer it in all cases, except in those of suspected malignancy, and those in which the fellow eye is deeply situated in the orbit.

Dr. Prince also exhibited a book for registering cases in which the ruling is so arranged that, by glancing at the page, it is possible to see immediately the number of cases of a given disease recorded.

DR. JACKSON stated that Dr. Williams, of Boston, was the first to record a case of evisceration. Dr. Williams was thereupon asked to speak on the subject.

DR. WILLIAMS regarded the pain ensuing after evisceration of the globe as differing from the ciliary neuralgia previously felt, in having such a character as might be due to edema and congestion of the conjunctiva and the orbital cellular tissue. He had been in the habit of evacuating completely the contents of the scleral cavity in cases of phlegmonous inflammation of the globe, and then—as also in excision of anterior portions of the globe in cases of anterior staphyloma or hydrophthalmia—of bringing the edges of sclera together with sutures. A very good stump, sometimes with little diminution in size of the globe, is thus obtained, which partly fills the orbital cavity and affords good support to an artificial eye.

### WHAT DRESSING SHALL LIE NEXT THE WOUND?

*Read in the Section of Surgery and Anatomy, at the Fortieth Annual Meeting of the American Medical Association, June, 1886.*

BY ROBERT T. MORRIS, M.D.,  
OF NEW YORK.

The combination of vaseline or oil spread upon any textile fabric represents the worst type of surgical dressing, because the unguent mingles with exuded lymph and retards organization of the latter; because the textile fabric entangles new epithelium cells and connective tissue cells; and because the moist condition of such dressing favors the development of troublesome micrococci. Lint and cotton are even worse than textile fabrics.

The cerates spread upon textile fabrics are one point better, because new epithelium cells are not entangled in the mass, but such dressings must not be employed nowadays.

Balsams spread upon textile fabrics or upon lint or oakum have a very limited field of usefulness. The dressing composed of the above mentioned elements is fairly antiseptic, but it does not avoid the danger of entanglement of new epithelium and connective tissue cells in a wound which is undergoing repair.

There are only two types of the perfect dressing. An iodoform covering for small exposed wounds represents one of these. Iodoform forms a thin, firm coagulum with lymph, and this is not readily destroyed by microorganisms. Moreover, even when a limited number of microbes are at work, the iodoform neutralizes the poisonous ptomaines which they produce, and thus removes an element of disturbance.

The other perfect dressing is the one which is required for the great majority of wounds, and it is composed of the following elements and for the following reasons. Let me say by way of preface that the surgeon is supposed to be familiar with the scientific antiseptic methods of to-day.

Immediately next the wound we must have a strip of the Lister protective oiled silk, which is furnished by all manufacturers of antiseptic supplies nowadays. New epithelium and connective tissue cells shoot along under this material without interruption, and it is the only material with which I am familiar that will prove wholly satisfactory. Gutta-percha tissue is absolutely waterproof and the wound beneath it looks sodden. Spun glass does not avoid the danger of entanglement of new repair cells; but the Lister's protective oiled silk allows of a sufficient transudation of moisture from the wound, so that the tissues beneath this dressing are not kept abnormally moist, and it presents a regular smooth surface to the dressings applied. Without the Lister's protective, it is almost impossible to obtain repair in a wound by the new method of clot replacement—but with the protective, after the employment of actual antiseptic methods of work, it is an easy matter to obtain repair in quite large open wounds in a very short time by the method of clot replacement.

Again, in skin grafting, the Lister's protective will make even pressure upon all parts of the wound, and when the dressing is changed we avoid tearing off the thin hyaline borders of new epithelium that have started in on their mission of repair. It makes a vast difference whether we apply a dressing in which this pretty new epithelium becomes entangled, or one under which the epithelium is allowed to attend strictly to its own affairs.

If we wish to apply the permanent dressing to a large suppurating surface and to stop suppuration it is difficult to accomplish our ends without

the alliance of the Lister's protective antiseptically prepared.

We must first destroy all of the pus and all of the microorganisms by pouring peroxide of hydrogen upon the suppurating surface. As soon as the peroxide stops foaming we know that the granulating surface is chemically pure. The strip of Lister protective, just large enough to cover the granulating surface, is then applied, and over it a bulky dressing of absorbent gauze or cotton. This dressing may remain in place untouched for several weeks if necessary, and it is possible to apply the dressing in such a way that not another drop of pus will be formed beneath it.

### FORCED RESPIRATION.

*Delivered in the Section of Practice of Medicine, Materia Medica and Physiology, at the Fortyeth Annual Meeting of the American Medical Association, June, 1889.*

BY GEO. E. FELL, M.D., F.R.M.S.,  
OF BUFFALO, N. Y.

Forced respiration is an advance upon artificial respiration. It will save human life where the latter will fail. This is now a clearly demonstrated fact, the cases treated by the author proving this conclusively. Four lives have been saved in America by the author and one in Vienna later by Prof. Dr. Boehm, of the Vienna General Hospital. In the first case 20 grs. of morphia were taken. After all known methods of resuscitation had been used, forced respiration was used for two and one-half hours and the life of the patient saved.

The second case took place in Vienna, Austria. In the third case 2 ozs. of tr. opii had been taken, all retained, and after artificial respiration had failed, forced respiration continued from 4 A.M. until 6:30 P.M., or fourteen and one-half hours, succeeded.

*Fourth case.* Tr. opii  $\bar{5}$ j taken, anterior jugular vein and trachea cut with razor, and a large amount of blood lost. Forced respiration produced; patient became conscious in four hours. Forced respiration kept up until 4 A.M., when  $\bar{5}$ vij of a salt solution of  $\frac{1}{2}$  per cent. was injected into left basilic vein by transfusion method. After twenty-one and one-half hours the patient first breathed freely for himself. In half an hour he requested that forced respiration be renewed for him, this was repeated and the patient made a good recovery.

The fifth case took place in a man 80 years of age who had taken  $\bar{5}$ j tr. opii. Forced respiration kept up for some twelve hours failed to produce recovery.

*Sixth case.* Child 18 days of age had been given by mistake of a physician 1 gr. of morphia, which was retained with all its serious effects five hours before respiration per tracheotomy was instituted. After about four hours' time it failed through heart failure to keep up life.

*Seventh case.* Morphia in large but unknown quantity taken. Operation undertaken after pulse at wrist was lost, pupils dilated, and auscultation failed to detect heart action; blood on tracheotomy venous. Forced respiration produced return of pulse at both wrists and clear action of heart on auscultation. Blood became arterial. Within about an hour it stopped beating.

*Eighth case.* Tr. opii  $\bar{5}$ j taken. Patient cyanosed, heart action weak, respirations about 1 per minute, dilatation of asphyxia taking place. Forced respiration for about eleven hours saved the patient. This last case occurred within this week.

The apparatus is simple, practical, can be used by any intelligent physician, and consists of a bellows to supply a steady column of air which passes through an air heating apparatus. The operation may be carried on in the open air. The apparatus connects with an air valve which controls the ingress of air to the lungs and is connected by an elastic tube with a tracheotomy tube which is placed in neck and trachea of patient.

The movements of bellows are utilized to control time of inspiration and expiration. The author believes that the operation should be used in cases where indicated, now that it has been demonstrated to be of value in saving human life.

### THE PRINCIPLES THAT SHOULD GUIDE US IN THE RATIONAL TREATMENT OF GONORRHOEA.

*Read before the Mississippi Valley Medical Association, September, 1889.*

BY BRANSFORD LEWIS, M.D.,  
OF ST. LOUIS

If we were to reckon progress in medicine by stages, we could select no more apt a term for designating the present one than that of the Stage of Bacteriology. Bacteriology has assumed such an important rôle in all that relates to medicine or surgery, that our attention is drawn to it in the consideration of almost every subject in medical or surgical science. And yet, dropping from this lofty plane of thought, which tempts us into the field of glittering generalities, and limiting ourselves to the more practical question at hand, let us inquire, what has this all-absorbing and comprehensive study and knowledge of bacteriology done for assistance in the treatment of gonorrhœa? Has the hope of aborting, of quelling, of exterminating the disease by a treatment based on the discovery, study and acquaintance with the life history of that sturdy villain, the gonococcus, been realized? Have the methods of treatment thus brought into vogue accomplished the great wonders expected of them? Have they accomplished anything

more than the palliation, to a considerable extent, of the severity of the disease, of shortening, somewhat, the duration of its several stages, and of doing away with the old and barbarous forms of astringent, caustic and stimulating injections? I believe that all those who have tried this or that new antiseptic, this or that "infallible germicide,"—not simply on two or three isolated cases, in which beautiful results may have been attained, and which, by the way, were in all probability not gonorrhœa; I say, that all those who have tried such new antiseptic plans of treatment in a number of cases are doubtless convinced that none are infallible; that all are subject to various influences, deleterious or favorable, that were met with in treating after the older, prudent methods.

Many beautiful and touching theories have been constructed to explain how the gonococcus would quail with fear when, in his revels, he should detect from afar the fumes of death-dealing iodoform, brought into action by means of this or that preparation; or how he would shrink with horror at the prospect of being literally boiled alive by hot injections; or washed out into the cold, cold world by the relentless flood of a prolonged irrigation; or of being crushed in spirit, body and soul by the continuous presence of a medicated gelatine bougie; or dried up into an Egyptian mummy of a coccus in the arid soil of a mildly astringent, antiseptic, non-irritating, magic healing, absorbent powder! But experience with these agents would seem to indicate that the usual rule of the breeding of contempt by familiarity is not broken in this instance. Nay, more. That the festive gonococcus after a time appears to become sufficiently acclimated to enjoy his surroundings, for a while, at least.

And this, notwithstanding the fact that antiseptics do kill gonococci, and with great certainty and facility—when they are in culture-fluids. But why not, when they are in the urethra, as well? For this reason: The gonococcus in preparing himself for the conflict does not foolishly remain where his foes can get at him with these various medicaments; he makes his landing and starts immediately for the woods, so to speak. He pushes on, by proliferation, between the epithelial cells, breaking through their connecting substance and finally ensconces himself below its deepest layers, along on the basement membrane, and even sometimes within and between the interlacing fibres of this structure. Here he proliferates and disseminates to his heart's content.

This has all been repeatedly and absolutely proved by eminent investigators. Bumm has watched the invasion of the conjunctival tissues by the hordes of gonococci; has seen them penetrate to the connective tissue layer, and has noted the strong obstruction offered by this tissue to their further progress. Not only this, but he has seen that the effect of astringents applied

over the epithelial surface serves only to constringe and harden this covering, which then, indeed, forms a secure protection against the absorption or leaking through of any germicide or antiseptic which, embodied in the injection or whatnot, has been applied to the mucous surface. Moreover, he has seen that the elimination of the cocci contained in this meshwork of cells and fibres is brought about, not by the penetration of the germicides into the tissues, there to attack the organisms in their strongholds, as has been thought by some, but it is accomplished by a process of proliferation of the connective tissue fibres into which gonococci are unable to penetrate, as intimated above. In the stage of improvement, these fibres, incited by the irritation present, increase in number, push forward, driving before them the microbes towards the surface of the membrane, from which they are washed by the outgoing urine, or killed by the germicides. When a sufficiently strong connective tissue bulwark has been constructed, new epithelial cells begin to dot the denuded surface here and there. The cocci have by this time lost much of their vitality and are unable to break them down with the ease shown at the first onslaught. The conditions for resisting their inroads, too, are then more perfect. They lie simply along the surface or among the superficial cells.

So that the final process of cure depends not altogether on the extermination of the few remaining gonococci, but also, and perhaps even more especially, on the closing of the tissues against their further invasion by the development of firm layers of this protecting barrier. And the inflammation then persisting may be interpreted as denoting the chronic irritation remaining after the severe disorganization wrought by the previous disease.

It is for these various reasons then, that in the earlier stages, when the gonococci themselves are doing the damage, the efficacy of antiseptics, germicides, astringents, etc., is limited to the position which they now occupy.

In order to overcome these impediments and give access of the medicines to the ambushed cocci, an enthusiastic Frenchman has recently suggested that the epithelial coat of the mucous membrane be scraped off by a brush-swab, on the plan commonly used in cleaning a pistol barrel; after which the urethra is to be douché with a powerful antiseptic solution. This method is original and ought to prove effective—in producing a stricture, if nothing else. It is certainly more energetic than any I should care to undertake.

I would therefore submit, that efforts at aborting or killing gonorrhœa with strong medicines, antiseptic or otherwise, not only do not attain the desired end, but are ill-advised and liable to be followed by unfortunate sequelæ or complications.

Consequently, treatment should be based on a plan having for its object the idea of carrying the disease through its various stages, as authors used to say, *tuto, cito et jucunde*; allowing the patient to experience as little discomfort, pain and annoyance as possible, mollifying the inflammatory reaction and destroying, devitalizing and discouraging the gonococci as much as our rather restricted powers will admit of; and hastening the healing process with all possible speed.

To accomplish these ends, having used various forms and modes of treatment, I have concluded that the one offering, with the general run of cases, the most advantages with the fewest objections, is that of giving in the first stage of the affection, simply alkaline diluents and sedatives internally, making use of such adjuvants as dipping the penis in hot water, etc., and in the second and third stages, giving injections of lanolin, medicated with an absolutely unirritating antiseptic, to which may be added in the third stage a mildly astringent and stimulating antiseptic.

As a means of introducing the ointment, I have been using, during the last six or seven months, this hard rubber applicator, which I present for your inspection. As you see, it consists of a catheter-like stem, perforated at its end, which is inserted into the urethra to the desired depth; a box to contain the ointment, and a piston which is screwed into the box, driving the ointment before it into the stem and thence through the perforations into the urethra. When properly performed, an injection given with this instrument causes absolutely no pain or discomfort for the patient. But sometimes a sudden movement on his part will jog the stem against some tender spot and evoke an immediate and earnest protest. To obviate this and to leave nothing undone that could in any way assist in avoiding irritation of any kind, I have had some vulcanized, soft rubber stems constructed, which answer the purpose very well. The square shape of the second (modified) box is of advantage in affording a surer hold on it. The stem need not be inserted as deep as its length will permit; the flex-

As to my reasons for preferring lanolin to other vehicles, I would say, that with reference to the other vehicles, water, the most common, is itself, in its purest state, irritating, and unless it contain some local anæsthetic, will cause pain; powders or tablets, though dry and absorbent when first deposited, soon become moist and cake up, losing the properties for which they were chosen. Gelatine bougies give pain at every movement of the body until they are liquefied; mucilages or emulsions present no advantages which are not possessed to a greater degree by lanolin, and—a point of great importance—all of them are lacking in “staying” qualities; with the first passage of urine, out they go, and in order to make their effect continuous, they must be renewed several times a day, entailing frequent repetition of the trouble, pain, etc., experienced each time.

Lanolin presents none of these disadvantages; it is wholly unirritating—is even soothing to inflamed tissues. When introduced pure, even without any pacifying sedatives, it invariably causes a feeling of relief and comfort to the patient who has been constantly reminded of his ailment by the teasing, harrassing sensation incident to all cases of gonorrhœa. As one patient remarked, the ease afforded allowed him to forget all about it for hours at a time, whereas, before he began to receive the treatment, it was never out of his mind while he was awake. I believe that the principal reason for this is, that it keeps the inflamed surfaces apart, preventing their continuous friction and auto-irritation. Actual pain in the urethra is also mollified by it.

The oiliness of lanolin assures its adhesion to the canal walls, even in spite of the flushing of the urethra by the stream of urine. It may be noticed floating on the urine of the second or third passage after the application. It is evident that in this respect, too, it surpasses all of the excipients named. An authority tells us that lanolin possessed antiseptic properties of no mean order.

I shall not take up more time in detailing its many advantages, which are almost self-evident.

As to the medicament employed, any remedy given in solution may be prescribed with equal propriety in lanolin. Of the various drugs which I have used, I sum up my impressions as follows: Bichloride of mercury, even in minute quantities is too painful or irritating, and frequently causes an increase in pus-formation; carbolic acid is also irritating, but not painful; iodoform might be used were it less perniciously active in its odoriferousness. The zinc preparations are applicable to the later stages, in which they give material assistance towards shortening the wind-up. Resorcin would be a most admirable remedy were it not a most aggravatingly unstable drug. If administered after it has degenerated, it will not be long ere the operator has cause to regret his ef-

ibility of the lanolin and elasticity of the urethral walls assure the spreading of the ointment over the inflamed area.

forts in the way of economy. Boric acid directly following the increasing stage of the affection, seems to fulfil every indication; it is an antiseptic, a germicide, and yet has absolutely no irritating effect upon the inflamed membrane. It is capable of killing the gonococci that it reaches, and of preventing attacks from other microbes which give rise to the secondary, or mixed, infection of Bumm. And, by the way, the continuous presence of medicated lanolin forms a vigilant guard against this complication.

Agreeing then with the dictum of all authorities of the present day, that gonorrhoea is a specific disease which cannot be aborted after it is once fairly started, I conclude that

1. Our treatment should not have for its object the futile idea of jugulating the disease in its early but established stages.

2. The endeavor to control its severity, to lighten in every possible way all of its disagreeable features, to shorten its course and to ward off complications, should be our guiding principles.

3. No local agent does its share in fulfilling these indications more perfectly than does lanolin, medicated after the manner suggested.

1006 Olive Street.

## MEDICAL PROGRESS.

A CONTRIBUTION TO THE HISTOLOGY OF THE CEREBRUM.—(By PROF. C. L. HERRICK, University of Cincinnati.) The striking results of recent investigations upon the physiology of various parts of the hemispheres, conflicting as they are, have given a fresh impetus to the study of the minute structure of the cortex. The interest manifested upon the subject is so wide-spread that the following notes are offered in advance of the paper in the preparation of which they were made.

In spite of the astonishing advance made during the last ten years in the knowledge of the anatomy of the brain, there remain a large number of questions of primary importance upon which nothing is known, or the testimony is so contradictory as to have value only as a stimulant to further investigation. Indeed, the most important question of all in this connection seems to have fared the worst.

The primary and permanent gain of experimental work has been the demonstration of the topographical distinctness of various motor and sensory areas in the cortex. The latest critical studies of Luciani and Seppilli leave no doubt that, however difficult or impossible it may be to sharply outline such areas, there are distinct parts of the cortex chiefly occupied with special senses and special groups of muscles.

If the occipital lobe be chiefly concerned with the function of sight and its intellectual concomitants, and the region about the crucial sulcus more particularly with the origin of voluntary motions of extremities, what more natural than to expect these areas to afford quite different histological elements to the microscope? Bevan Lewis has demonstrated that such a difference actually exists, and with masterly skill has pointed out and illustrated the characters of the motor areas. His figures of the cortex of the limbic lobe and region of the crucial sulcus are certainly beautiful, and amply reward the patience of the author. The last papers of this writer which reach us do not, however, indicate that the distinction between motor and sensory areas, bears any correspondence to the facts of physiology; that is, although the presence of large ganglionic cells in motor areas and their absence elsewhere is important, it does not afford a clear idea of the direction which the stimuli pursue in being transformed from sensory to motor phases. To say the motor areas possess a five-layered cortex and the sensory a six-layered is an advance, inasmuch as we are able to distinguish microscopically the two sorts of areas and concentrate attention more closely upon the intimate structure; yet we cannot discover why a five-layered mass of cells serves the motor function better than a six-laminated cortical area; neither do we see any clue to the problem as to the way in which these areas affect each other. Moreover, the naming and numbering of cortical layers is necessarily arbitrary, and along the distinct boundaries it is impossible to sharply distinguish motor from sensory cell-chains.

Luys has positively announced a very different basis for distinguishing the sensory and motor cells. Making no topographical distinctions, he simply declares the smaller superficial cells of the cortex sensory, and the deeper ganglion cells (including the "giant cells") motor in function, somehow deriving the fibers passing to the former from the thalamus, and sending the descending processes of the latter to the corpus striatum. This has seemed to impress most critics as somewhat mythical, and really the difficulties in the way of demonstrating such minute connections seem unlikely to yield to methods like those employed by our author.

The present writer, in the midst of a series of investigations, undertaken in connection with Prof. W. G. Tight, of Denison University, upon the anatomy of the brain of rodents and lower mammals generally, has been led to believe that the attentive study of these simpler brains affords a solution of this most important problem of cerebral histology. The work is but begun, yet its results upon this point seem worthy of a preliminary abstract.

The subject chosen was the ground-hog, *Arctomys*

*tomys monax*, while the brains of rabbits, opossums and raccoons served for comparison. The functions of the cortex were investigated by electrical stimulation and extirpation. In this way the motor centers for the fore and hind legs, the muscles of the face and neck and the sensory areas were accurately diagramed. A method used by us for the first time may be incidentally mentioned as worthy of more careful employment. As the electrodes were removed from the brain a small pasteboard or wooden peg bearing a number was inserted, and the reaction produced at this point was carefully recorded upon a diagram of the surface of the hemisphere with the corresponding number attached. After the removal of the brain these tags served to check the accuracy of the diagram and a careful drawing was made, including the areas experimented on.

The brains were placed in chromacetic solution twenty-four hours and then in alcohol, and continuous series of sections in various directions mounted in balsam. Several hundred such sections were prepared and studied by the method of geometric reconstruction from camera drawings and measurements.

To briefly summarize the facts elicited upon this point, it may first be stated that over the entire recognized motor area and along the limbic lobe, or region along the median fissure, a well-defined type of structure can be observed, while the remainder of the cortex contains an entirely different set of cells. In the motor area the cortex resembles that described by Bevan Lewis in the sheep and pig, though the minor subdivisions are less distinct. The outer neuroglia layer is followed by a zone of small pyramidal cells with a strong axial process derived from the superficial layer and fine anastomosing fibrils from the lower and blunt extremity. Below this is an indistinct layer of fusiform cells, which connect below with the "giant" or ganglion cells, which are not only more than twice as large as the other members of the series, but are nested or clustered and have peculiarities of form readily distinguishing them. The axial process is strong and may be traced upward a considerable distance. The numerous inferior processes of these giant cells connect with multipolar, parametric, or irregular cells lying upon or imbedded in the white fiber zone. Occasional anastomosing of cells of the same level can be detected, but the connection seems generally to be between cells of different orders.

Now directing our attention to the cortex in portions known to lie within the sensory area, we find an entirely different type of cell arrangement. In general, the sensory, or, preferably (not to prejudice their function), centripetal, cells receive the stain less readily and are only visible in good preparations; but distinctions based on receptivity to stain are untrustworthy. The cells of the

upper zone, lying next the neuroglia layer, are nearly of the same size as those of the corresponding zone of motor areas, but are more nearly globular, possess a larger nucleus, and, in particular, *receive their axillary process from below*. Cells of this sort occupy the entire thickness of the cortex to the depth of the giant cells, the only variation observed being an increase of size downward. Corresponding to the giant cells of motor areas are large pyramidal cells, each with a slender downward projection terminating in an axillary process, while the *upper* blunt extremity gives off numbers of fine fibrils. Thus the contrast is complete, the course of the chains of cells being completely reversed, and we seem warranted in assuming that there is a similar variation in the direction of the stimuli traversing these chains.

We hasten to explain that this variety of cell which is termed centripetal is by no means limited to circumscribed areas exclusive of all centrifugal or motor chains. On the contrary, there are numerous centrifugal cells scattered in groups within the area chiefly affected by the centripetal variety, and, *per contra*, the centripetal variety is sparsely scattered among the undoubted centrifugal elements of the motor area. Nevertheless, in those areas ascertained by electrical stimulation and extirpation to be sensory the centripetal variety greatly preponderates, and in the optic centre quite excludes the other, while in the motor centres the other type occupies the prominent rôle. To carefully test this point, sections taken through an isolated motor area surrounded by a zone indifferent to the electrode were sought. Such an opportunity is afforded by the centre to the sphincters of the face, which can easily be located in rodents. This spot lies well back of the centre for the hind leg, and near the median line. The existence of a sensory centre for the *orbicularis palpebrarum* was postulated by Munk as the result of extirpation. (This area lies in what Munk would call the "independent sensory region of the eye," not seeming to recognize that there existed a true motor area for the sphincter. This latter fact appears demonstrated by our very definite results. The zone is very small and accurately defined, but its stimulation, even with a feeble current, induced violent and long contraction, not only of the *orb. palpebrarum*, but apparently of *orb. oris*. Cf. Munk: "Ueber die Functionen der Grosshionrinde," Vierte Mittheilung, p. 64.) Transverse sections passing through this centre bring out the distinction between the motor and sensory areas. In that region shown to govern the sphincter the centrifugal cells are abundant, but laterally beyond its limits the centripetal predominate.

Upon the posterior aspect of the occipital lobe motor cells are numerous, as along the limbic lobe. Near the gyrus fornicatus the centripetal type pre-

vails, and in the external part of that gyrus, but internally groups of peculiar multipolar cells traverse the cortex in all directions, requiring further study and affording evidence of the extensive disturbance due to the fold producing the ammon's horn.

One familiar with the recent literature of this subject will note that the facts here adduced correspond closely with the conclusions of the most careful experimental observers. Meynert quotes with approval Munk's conclusion "distributing sensory areas over quite the whole of the cortical surface, and therefore terming the region from the occipital lobe to near the frontal margin the 'sensory sphere' of the brain."

It is strange, however, that such distinctions as are here claimed should not have been previously noted, and this naturally will cast doubt upon these statements, which, however, can be amply supported by camera drawings or actual sections. The greater avidity with which the centrifugal cells take the stain explains why imperfect preparations demonstrate one class only, and the wide distribution of the motor type may have prevented any serious search for another structural modification.

It may be left for subsequent examination to decide what becomes of Meynert's theory that "in order to explain volition it is only necessary to postulate sensations of innervation, and tactile and pressure sensations are thought to be a means of regulating the excitation of sensations of innervation" (Meynert, "Psychiatry," p. 145). But if we can demonstrate in the cortex afferent and efferent projection systems, and distinguish the cells occupied with psycho-motor and psychosensory processes, certainly a great step is taken toward an intelligible construction of cerebral mechanics.

**THE DRY METHOD OF WOUND TREATMENT.**—In an address delivered to the German Congress of Surgeons DR. LANDERER, of Leipzig, advocated what he calls the dry method of wound treatment, consisting of the use of pieces of dry aseptic gauze in place of moist sponges and irrigating fluids in surgical operations. Pieces of this gauze are also placed on any portion of the wounded surface not under manipulation at any time during the operation, for protection and as a hæmostatic. No fluid whatsoever is permitted to come in contact with the wound at any time. He approximates the surfaces carefully by deep and superficial stitches, but uses no drainage; neither does he leave the ends of the wound open.

He is scrupulously careful in rendering the surgeon's hands and those of his assistants, the instruments and the field of operations absolutely aseptic, and keeping them so throughout the operation. He has had primary union in ninety consecutive cases, including abdominal sections,

amputations of breasts, extirpations of tumors and glands, castrations, hydrocele operations, osteotomies, nerve-stretching, plastics, resections, amputations, etc. The advantages claimed for the method are: 1. The patient is not exposed to wet and cold. 2. The loss of blood is minimal. 3. Absorption of antiseptics is not possible. 4. Time of operation is decreased. 5. Rapid recovery, only one dressing being necessary, and that only if non-absorbable stitches are used. 6. Great convenience, especially for country practice. 7. Saving of surgeon's hands.—*Langenbeck's Archiv für Klinische Chirurgie*, vol. 39, heft. 1.

**INOCULATION OF CARCINOMA.**—(Dr. Wehr. Paper read before the Eighteenth German Congress of Surgeons, published in *Langenbeck's Archiv für Klinische Chirurgie*, vol. 39, heft 1.) DR. WEHR made a series of experiments upon twenty-six dogs by taking pieces of carcinoma of the vagina or penis and inoculating them subcutaneously through the shell of a trocar upon healthy animals. In most cases the nodules failed to grow, or if they grew at first they became atrophied later on; but in one animal, which was inoculated December 12, 1887, the tumors grew constantly until the animal died June 16, 1888. The autopsy showed the tissues surrounding the points of inoculation infiltrated with carcinomatous tissue, and the pelvis filled with nodules, some of which exceeding the size of a hen's egg. These tumors had occluded the urethra, causing a rupture of the bladder by overdistention, and this causing death from hæmorrhage. There were also metastases in the spleen and infected lymphatics in the chest.

**SUBNITRATE OF BISMUTH IN ERYSIPELAS.**—M. MARC SÉE has been using for several years a permanent antiseptic dressing of which subnitrate of bismuth is the essential element. During this time he has not seen the development of a single case of erysipelas when the dressing was used, although the surroundings of the patients were often such as to favor its appearance. In certain operations, where wounds are left which are evidently not in an aseptic condition, he abstains from the scrupulous use of antiseptic douching, and relies upon the bismuth, with which the wounds are filled, after which he applies a layer of hydrophile wadding. He has also had reason to believe that bismuth is a very useful application in cases of erysipelas already developed.—*La Semaine Méd.*, Aug. 28, 1889.

**FRAULINA SCORBILIS IN DYSENTERY.**—DR. APHEL employs the powder of fraulina scorbilis in doses of seven grains every two or three hours. It is indicated chiefly in adynamic forms of the disease.—*Los Avisos Sanitarios*.

SATURDAY, OCTOBER 12, 1889.

THE PHYSIOLOGICAL RESISTANCE OF THE  
PERITONEUM TO INFECTION.

In the past year hardly a more interesting series of experiments has been made in the interest of surgical pathology than those of RINNE.<sup>1</sup> Practically and clinically it has been demonstrated that the peritoneal cavity under certain unknown circumstances has the power of taking care of a vast amount of filth. It remained for Rinne to harmonize observed clinical facts with *a priori* deductions.

He found that large quantities of septic material and pure cultures of pyogenic bacteria were absorbed, although injected daily into the peritoneal cavity of animals, provided that the peritoneal surfaces were uninjured. The injections produced only mild symptoms in direct proportion to the quantity of septic material used, and in no case was there more than a moderate rise of temperature. The results were very different when there were coincident defects in the peritoneum, exposing the subperitoneal connective tissue to infection. Then there invariably appeared progressive suppurative peritonitis going out from the infected connective tissue, which usually terminated fatally.

The practical import of these experiments can hardly be over-estimated. They explain why the escape of pus into the peritoneal cavity from the rupture of a pyosalpinx is not necessarily fatal if the tube is promptly extirpated, and the wound and stump properly treated. They point out that the incision is the point of greatest dan-

ger in all abdominal operations, and they would indicate that too much care can not be taken in coaptating the peritoneal edges of the wound. They explain why the removal of abdominal tumors is so much more dangerous after adhesions have taken place, because the resulting denuded places offer less resistance to the invasion of septic bacteria. They explain the success of those operators who disregard the dictations of scientific bacteriology, and also the recovery of patients after abdominal section by horned animals. They teach us to consider cautiously the evidence presented by the statistics of operators, and await the demonstration of more exact methods as to the import of their results. They warn us that clinical evidence is inadequate to overthrow the deductions of experimental physiology and pathology, and that our time is provided with methods of precision which are yet imperfectly improved. They beckon the ambitious into fields of activity and thought far less crowded, though more promising than the operating room and the dead house.

The resisting and absorptive power of the peritoneum is beyond that of any other serous cavity. This is as we should expect. The peritoneal surfaces are only a line distant from the most filthy and prolific culture medium about the body. It is connected with this seething and turbulent mass by the most active absorbent lymph channels. Doubtless it is frequently invaded by septic bacteria from the intestinal contents. From these frequent invasions an immunity has been developed which has been perpetuated and transmitted by the working of the ordinarily recognized laws of evolution.

Again we are taught to consider the causes which determine the localization of infection, as more important than the quantity and quality of infective material. Doubtless traumatism is one of the most important of these causes, but we must not forget that the depression of the general temperature of the body, the interference with nutrition, and general *malaise* frequently observed after operations, are factors which may speak for the life or death of our patient. Not only should the abdominal section be made with the greatest attention to cleanliness, but the peritoneal edges must be accurately coaptated, the operation must be done with the greatest celerity and delicacy, and depressing influences of star-

<sup>1</sup> F. Rinne, Langenbeck's Archiv. für klinische Chirurgie. 39 pp. 1-66.

vation, over-medication, and deprivations of every kind must be avoided if we would eliminate all those causes which determine the localization of that infection, which is still the greatest danger the operator has to meet.

#### HYPNOTISM IN THERAPEUTICS.

This seductive method of treatment is still on the increase. Its exponents are for the most part more enthusiastic than ever. The therapeutical practice of hypnotism is no longer circumscribed by the narrow confines of France. It has spread throughout Continental Europe. Its progress has not been stayed by that watery Gibraltar, the English Channel, but sailing across has laid hold upon the insular conservatism of Great Britain. It has reached Germany, Sweden and Russia. It has scaled the Alps from all sides and wellnigh taken Switzerland by storm. It is more popular in staid Holland than in France. America alone has thus far escaped—but we expect it soon as we do all widespread contagion. Let us see, then, to what we may look forward. Hypnotism, not long since wrested from the hands of charlatanism, is held as a trophy by the medical profession. What we know of it in this country is mainly what we have learned of its employment by Charcot in the Salpêtrière. At present, however, there are in France two schools of hypnotism—that of Nancy, with Bernheim, Liébault and Liégeois as its principal champions, and that of Paris, where its practice has been developed under the influence of Charcot. The former school is by far the more radical, and its teachers claim the wider field of applicability for the method.

Nearly thirty years ago Dr. Liébault began to treat dispensary patients in Nancy by a system which he elaborated and termed "Treatment by Suggestion." In 1866 he published a book in which he gave a full description of his various methods, together with a report of cases successfully treated. Nevertheless he remained for many years a prophet without honor. In 1884 Prof. Bernheim, of Nancy, although skeptically inclined, began an investigation of the subject with the result of soon becoming a convert, and in 1884 he published his classical work, a second edition of which has recently appeared in this country, bearing the title, "Suggestive Therapeutics. A Treatise on the Nature and Uses of

Hypnotism." Hitherto the English language has been practically without a literature on this subject. To Liébault is due the credit of having founded a school of practice which has found representatives throughout Europe. The interest in the entire subject, which has been gradually increasing, and which has been fostered by discussions in the medical societies of various European cities, has finally culminated in a "Congress of Hypnotism" held at Paris, where congresses of all possible descriptions have been unprecedentedly numerous of late. At this Congress the forces were marshalled under the leadership of the aforesaid schools of practice. The Nancy contingent, with its radical views, was well equipped and ably generated by Prof. Bernheim, whose paper on the "Therapeutical Value of and the means of Inducing Hypnotism" served as a point of departure for a pretty lively dispute.

The principal differences between the two schools may be briefly explained. In the first place, the Nancy school believes that hypnotism is a physiological condition; the Paris school insists that it is a neurosis. The Nancy school thinks that pretty much all the manifestations of hypnotism are produced by suggestion and that the hypnotic state is so produced. The Paris school complains that hypnotism and suggestion are two separate things, and that Prof. Bernheim is so absorbed in *suggestion* that he has lost sight of hypnotism altogether.

These are some of the victories claimed by the champion of Nancy: Nearly all the tedious and rebellious cases of hysteria; cases of nervous anæsthesia, hyperæsthesia and amblyopia almost instantly relieved; pains from lead poisoning, neuralgia and rheumatism instantaneously or very quickly subdued; chronic rheumatic arthritis cured; pleurisy pains removed in one or several sittings; chorea quickly cured or greatly shortened in its duration; menstruation regulated, checked or made to appear at a fixed date; spinal disease ameliorated; an obstinate case of vomiting of long standing cured in two weeks; a case of cerebro-spinal sclerosis with palsy and staggering relieved for a long period; an old and most obstinate case of migraine with insomnia cured in three weeks, etc.

Charcot, however, holds very different opinions. Without wishing to deny that in cases of organic disease of the nervous system hypnotic suggestion

may, in certain cases, result in a degree of improvement, he is convinced that this occurs only by mere accident, and that, in such cases, the methods of suggestion have no claim to be regarded as therapeutical measures. On the other hand, in cases of hysteria in women and in individuals markedly susceptible to hypnotism in its stage of somnambulism, good results may reasonably be expected. As for hysteria in men, one must express one's self with greater reserve and beware of insisting upon a method which is very far from giving good results in all cases and may, indeed, produce exactly opposite effects with very disagreeable consequences. One should deal with hypnotism as with all other therapeutical measures; it has its indications and its contra-indications, and if one fails to employ it in a judicious manner the results are apt to be disastrous. Charcot's application of hypnotism has been confined to neurotic patients, and even with them he seems of late to be somewhat less enthusiastic than formerly.

It is, however, from the Nancy school that we receive the most glowing accounts of cures by hypnotism. As for the other side of the question, we hear but little from the opponents of hypnotism in France, where, if the subject is mentioned at all, it is spoken of in terms of praise.

In England a variety of opinion is expressed, much of which is favorable to the method. In connection with a paper read at the recent meeting of the British Medical Society by Dr. Voisin, of Paris, several English physicians reported successful cases, while others admitted having received a favorable impression by witnessing its action in England and France. Dr. C. L. Tuckey has also written an interesting brochure, entitled "Psycho-Therapeutics," a large part of which is taken up with an ingenious argument of inductive reasoning with a view to explaining the phenomena of hypnotism.

In Germany, although there is a growing interest manifested in the subject, there is not wanting an expression of wholesome caution and distrust, as indicated by recent expressions from writers of eminence, some of whom do not hesitate to pronounce hypnotism a very dangerous agent. Among those in Germany who are very decidedly opposed to hypnotism may be mentioned Prof. von Ziemssen, who, as the result of a series of experiments conducted by his assist-

ants, has reached the conclusion that hypnotism exerts little or no beneficial action even in cases of slight functional disturbance, while it is positively injurious to many patients. He believes that to employ the method as a therapeutical measure in cases of slight functional disturbance is like gunning for sparrows with cannon balls for ammunition, while its repeated application is apt to convert the milder forms of hysterical manifestations into the *grande hystérie* of Charcot; in the severer forms of diseases it is a mere substitution of one form of mental disorder for another, and is akin to curing one of the morphine habit by giving him cocaine. He trusts that the good sense of the medical profession in Germany will restrain it from countenancing so dangerous a procedure.

There can be no doubt that the elements of faith and expectancy are prime factors in the solution of this problem, just as they are in the somewhat allied methods of faith cure, mind cure, prayer cure, and, may we not add, in *classical* homeopathy as well. Expectancy of cure in the mind of the patient is one of the most potent allies of therapeutics, and one which the physician ought never to disregard or underestimate. As for hypnotism itself, it will be well for all who are inclined to experiment with it to remember the failures and dangers that have already been encountered, and not blindly trust the voice of mere enthusiasm.

#### EDITORIAL NOTES.

##### HOME.

**CHRONIC INVALIDISM.**—An invalidism of unusual duration has appeared in the telegraphic columns of the daily press, as follows: Miss Ann Jones died recently at Jaybridge, Me., aged 87 years. She had been an invalid for seventy years and had been confined to her bed for sixty years. Her mind was clear to the last. We sometimes hear our medical friends use the careless tautology of "old chronic cases;" if it were permissible ever to use that expression it would be in such a case as this.

**PRELIMINARY EXAMINATION OF STUDENTS.**—The Regents of the University of the State of New York, through Professor Melvil Dewey, their Secretary, have been taking steps toward the carrying out of the law of 1889, which re-

quires certain students of medicine to pass examinations preparatory to entering upon their professional studies.

IMPROVEMENT OF JEFFERSON MEDICAL COLLEGE.—The Jefferson Medical College and Hospital at Philadelphia will soon add a building to the group already located at Tenth and Sansom streets, as the needs of the college and hospital have increased to such an extent that the Board of Trustees have found it necessary to have another building.

DR. R. A. LANCASTER, of Gainesville, Fla., has been elected President of the Alachua County Board of Health.

THE *Sanitary News* says: "The need of the times now is the thorough dissemination of the knowledge that sanitary science has made available for the promotion of the public health."

THE CHICAGO MEDICAL LIBRARY ASSOCIATION, incorporated last month for the purpose of securing and maintaining a library for the advancement of the medical and kindred sciences, held its first regular meeting on Oct. 4, at the Grand Pacific, at which the following were elected officers: President, Dr. N. S. Davis; Vice-President, Dr. Edward A. Lee; Secretary, Dr. Bayard Holmes; Treasurer, Dr. E. Ingals. Dr. William F. Smith was made a Director in place of Dr. Mary H. Thompson.

A GOOD LAW, and one which should obtain in every State in the Union, has been passed by the New York State Legislature. It reads: "Before the Regents of the University of the State of New York, or the Trustees of any Medical School or College within this State, shall confer the degree of Doctor of Medicine upon any person who has not received a Baccalaureate Degree, in course from a College or University duly authorized to confer the same, they shall require him to file with the secretary or recording officer of their University or College, a certificate showing that prior to entering upon the prescribed three years' study of medicine, he passed an examination conducted under the authority and in accordance with the rules of the Regents of the University of the State of New York, in arithmetic, grammar, geography, orthography, American history, English composition, and the elements of natural philosophy, and such certificate shall be signed

by the Secretary of the Regents, and countersigned by the Principal or Commissioner conducting the examination."

HUXLEY furnishes September with a reflection having an R in it, addressed to those who have recently resumed the consumption of bivalves: "Very few persons, I suppose, imagine that when this slippery morsel glides along the palate, they are swallowing a piece of machinery far more complicated than a watch."

#### FOREIGN.

POST-GRADUATE INSTRUCTION IN LONDON.—In a recent number of *The Lancet* appears the announcement that an effort will be made this year to inaugurate a post-graduate course at some of the London hospitals, like the Moorfields Ophthalmic Hospital, at which there are no clinical classes. The proposed course will be entirely practical and for qualified practitioners only; it will cover three terms of eight weeks each, and the fee will be ten guineas.

DEPOPULATION OF FRANCE.—The *British Medical Journal* says: "The movement of population in France indicated by the summaries published for 1888 in the *Journal Officiel* cannot be read without regret. They are summed up pithily by M. Georges Michet in a few words: Diminution of marriages, augmentation of divorces, decrease of legitimate births, increase of illegitimate births, excess of deaths over births in forty-four departments. In 1888 only 276,848 marriages were celebrated, 6,360 less than in 1883 and 8,719 less than in the period 1847-1860. The number of divorces was 4,708, or 1,072 more than in 1887, and 1,758 more than in 1886. The number of births has considerably diminished. In 1888 there were only 882,639 births; this is a diminution of 16,749 births compared with 1887, of 41,919 compared with 1886, of 42,000 with 1885, of 55,119 with 1884. The proportion of illegitimate births, which in 1882 was 7.5 per cent., is now 8.5 per cent. It is very unequally distributed; thus, in the Department of the Seine it is 25 per cent., while in Brittany it is 2 per cent. But for the afflux of illegitimate births, the French population, says the official report, would decrease. The excess of births over deaths amongst the foreign residents in France is 11,000, one-fourth of the total excess for the whole population."

## TOPICS OF THE WEEK.

## MEDICAL SCHOOLS IN CANADA.

At the annual meeting of the Canadian Medical Association, held at Banff, N. W. T., August 12, 1889, the president, DR. H. P. WRIGHT, in his annual address, refers to Canadian Medical Schools as follows :

"Of our medical schools in Canada we have good reason to feel proud. They are under the care and management of thoughtful, hard-working and self-sacrificing physicians and surgeons. In most instances the teachers are necessarily active practitioners, for few in our ranks have private means, and the instructors' pecuniary rewards are but pittance. As a country we do feel proud of our schools, and, as a people, grateful to our teachers; but, we know, that as institutions they are not yet perfect. These imperfections are not faults controllable by the teachers; they are the silent appeals to the wealthy and philanthropic. To quote from Dr. Alfred L. Loomis in his magnificent address to the New York Academy last year: "Why is it that men of wealth do not realize their great opportunities for wise liberality in this direction, liberalities which will not only shed lustre upon themselves, but will mitigate the sum of human misery as certainly, and in many ways far more effectually, than our hospitals and charities for the sick and suffering poor." He blames the profession for not having tried to direct the stream of accumulated wealth in this direction, for "next to religion, education is the cornerstone of our civilization." Then, after alluding to the noble gifts recently made to some of the medical colleges, he is inspired by the hope that the stream of emotional benevolence for the sick and suffering is being turned into intellectual channels for educational needs. We have not yet to complain of emotional benevolence, as they have in the city of New York, where they have so many hospitals and dispensaries that patients are at a premium; but we know that public attention has not been sufficiently directed towards the endowment of chairs in our educational institutions, for the provision for scholarships to help on the needy and industrious student, or for the establishment of a general fund for the purpose of erecting and maintaining laboratories at different points to further original investigation and research. All these are necessary if we are to have a perfect system of medical education 'in order that those who teach may, by personal and familiar contact, gain such intimate knowledge of each student and firm control of his mental processes' as will enable them to become teachers in the good old Anglo-Saxon sense—to be educators, and not simply instructors 'pouring out their daily dole of wisdom into unresponsive ears.' "

Within the past year several strong appeals have been made through our medical press, in favor of more practical instruction, and that every student may have books in his possession giving a careful digest of the subject he is studying. The teacher's duty, in so far as the method of imparting knowledge is concerned, is changed. When books were scarce and biology was a nursing twenty or twenty-five years ago, didactic teaching was a

necessity and note books were valued possessions. Now, our teachers should be expert demonstrators, appealing largely to the senses in the hospital wards and laboratories.—*Montreal Medical Journal*.

## WAKEFULNESS IN NEURASTHENIA.

A wide range of opinion on the management of this condition found expression at a recent meeting of the Epidemiological Association. The use of drugs, with the exception of sulphonal, perhaps, did not find much favor with the members. Some of them had found that their patients of this class slept when they were at the seaside, while others recommended the Colorado atmosphere. Some patients had been found to be able to sleep at sea, but not on land. The weight of evidence seemed to favor the resort to mountain air for patients who were anæmic, with a presumption in favor of sea air for those who were plethoric. Dr. Solly, of Colorado Springs, has found that a large proportion of anæmic neurasthenics find sleep on the mountain heights, but this cannot be said of the entire class. It is not improbable that other conditions besides those of climate enter into the account where the patient travels from our Eastern cities to the Rocky Mountains in pursuit of sleep. The jaded matron leaves the worries of the household, and the business man, broken down by the rush of daily cares, finds many things changed besides the atmosphere among the far Western altitudes. Still, as a rule, the climate gets all the praise when an improvement takes place. Business men from the East report a larger percentage of recoveries than the matrons, however, probably because fewer of their anxieties can follow them. Improvement in the assimilation of food, it should not be forgotten, goes a great way toward sleep production in those who are affected with derangement of the nervous system; and this is one of the frequent accompaniments of any change of scene and environment. Not that there is always any marked increase of appetite or in the amount of food taken, but there is an appropriation of the food by the nervous centres, to their consequent strengthening. It is often a prominent feature in neurasthenia that the food may be taken in and digested fairly well, but stops short somewhere in its distribution to the tissues and is largely wasted. Ordinarily, when this waste ceases there is a corresponding abatement of wakefulness and other neurotic symptoms.—*New York Med. Journal*.

## THE FUNCTIONS OF THE CEREBELLUM.

Is the cerebellum an organ for the storage of cerebral events which have become automatic? Do we first of all receive with the cerebral cortex and then practice with the same brain-bark, and afterward relegate to the cerebellum, as to a limbo, those things of which we are so tired of being conscious? Are all performances of the cerebral cortex conscious acts, and those of the cortex of the cerebellum unconscious? And so might questions, more or less unanswerable, be postulated without end. The functions of the little brain are scarcely known at all; even the dependence of the equilibrium on its existence may be called in question on the data supplied by

pathology. It is perfectly certain that no obvious signs of nervous disease need exist when the lateral lobes are the seat of even extensive mischief. Some regard the cerebellum as the terminal organ of all visceral sensation, and on this assumption it has been thought that the curious perturbations in visceral epilepsy are to be ascribed to perversions of the vitality of the gray matter of the little brain. Anything is possible for the cerebellum. The most gifted imagination might guess strange things, yet pathology could perhaps find exact counterparts.—*Lancet*.—*N. Y. Med. Journal*.

#### HOW THE LEPROSY BEGAN IN HAWAII.

The Hawaiian consul in London sends an interesting sketch of the history of leprosy in Hawaii and the leper's island of Molokai. The first known case of true leprosy (I cannot speak as to elephantiasis) occurred, he writes, in the islands more than forty years ago.

It has been supposed to have been introduced by a Chinese; but this was never established; and it may here be remarked that the ratio of leprosy among the Chinese residents is less than that among the natives. In twenty years the disease has attacked a large proportion of the Hawaiian population. In 1865 as many of the lepers as could be induced to go were taken to a beautiful valley in the island of Molokai, not to be called, as was that of Rasselas, a "happy valley," but fertile and eminently adapted to its purpose. Before it was the ocean, and landward the plain was shut in completely by a mountain range, in which were precipices 3,000 feet high. Doubtless at first some disorder and a want of organization existed. But the Hawaiian Board of Health began its work and improved matters. Pure water was brought into the settlement from sources a mile distant in abundant quantities, and was distributed by exits in nine different situations.

In the year 1873 Mr. Ragsdale, a layman, gave an example of self-sacrifice by volunteering to act as superintendent to the leper asylum. He did efficient work there, but did not live long. It is to be admitted that the housing of the sufferers was for some time bad and insufficient. Yet, in 1874, Mr. Widemann, President of the Board, asserted that, "in a material point of view, the people were better off in Molokai than most natives of the islands, and also better, with few exceptions, than they ever were in their own homes. Parcels of land and wooden houses had been bought for the increasing population, and 6,000 feet of waterpipe had been laid." Next the settlement was divided, and the two establishments of Kalawao and Kalaupapa were placed at a considerable distance from each other. In 1879 and 1880 there were in the former of these places 802 lepers, of which 458 were men and 344 were women. There has always been an excess of cases among the males. The largest number at any one time appears to have been 1,000. In the year 1874 the young Belgian priest Damien cast in his lot with that sad society, and was appointed assistant superintendent. The lepers cultivated plots of ground and occupied themselves in such manual labor as they were capable of.

The biennial grant of the government is \$100,000 for

Molokai and \$35,000 for the establishment on the Island Oahu. There is a resident surgeon at Molokai.

The present king and queen have shown great interest in and sympathy with the lepers. Three years ago they paid a memorable visit to them, and a hymn written for the occasion by the king was sung enthusiastically by the patients. I have understood that the resident medical officer, Dr. Hoffman, is himself affected by the disorder. I will add that the ratio of deaths in a year is 58 per 1,000, and the disease runs its course after first incubation in about eleven years. I need hardly say that all kinds of remedies are being tried on the sufferers, and I must express my thanks to the English government, who procured at my request from the government of India, a large quantity of Gurjun oil, which I forwarded to Hawaii. It has been thought that this oil is the most potent agent, if not for the cure, for the restraint and alleviation of leprosy.

#### A LEFT LUNG WITH AN ACCESSORY LOBE.

DR. WM. A. EDWARDS, of San Diego, reports a case as follows: The lower lobe is of the usual size and formation, but the upper lobe is sub-divided at about its middle into two distinct lobes; the lower of these is remarkable in that its so-called cardiac loblet is unduly developed, encroaching upon the cardiac triangle, and removing the heart from the chest wall. The supernumerary lobe is formed altogether at the expense of the upper, which is not at all decreased in size, but is simply fissured throughout its upper segment; the increase in size is occasioned wholly by the prolongation of lung tissue above referred to. The entire lung was functionally active, and its histological character the same throughout. In 1885 Dr. Edwards reported the second case on record of an accessory lobe of the right lung. Accessory lobes of the left lung have been more frequently observed.—*Pacific Medical Journal*.

#### THE JOHNS HOPKINS UNIVERSITY.

PRESIDENT GILMAN has authorized the announcement that there is no foundation for the rumor that the university is in financial difficulties. The salaries of the president and professors have not been cut, and several new appointments have been made. While it is true that the income from the Baltimore and Ohio Railroad bonds has been cut off, yet there is an accumulated income from former years, the receipts from tuition average \$40,000, and \$108,000 is available as an emergency fund during the coming three years. Within six months the university has received \$300,000, and other gifts are expected. The hospital funds are distinct from those of the university, and are so invested that the income is an assured one.

#### ST. JOHN'S GUILD.

The report of the past season's work by the St. John's Guild, of New York, shows that over 30,000 children and mothers were received on the floating hospital, and 1,500 sick children and others were treated at the Cedar Grove Seaside Hospital belonging to the Guild. The expenses exceeded the receipts by \$3,000.

## PRACTICAL NOTES.

### AGARIC ACID: A NEW DRUG FOR NIGHT SWEATING.

Some years ago a substance derived from the well-known *Agaricus albus* was introduced as a sweat-checking agent in phthisis (*Practitioner*, xxix, 321). It was looked upon as an alkaloid body, and received the name of agaricine. This, however, has now been found to be an impure substance, and Professor Schmiedeberg has recently extracted from it a triatomic dibasic acid, to which the name of agaric acid has been applied. This is a white, silky, crystalline substance, scarcely soluble in cold, but readily so in boiling water. Hofmeister has recently investigated its physiological effects, and shown that its action is upon the centres in the medulla, especially the vagus and vaso motor. It possesses no mydriatic action; on the contrary, instillation of the sodium salt of the acid produces slight narrowing of the pupils, probably from mechanical irritation. The influence of the substance on the secretion of sweat is not a central one, but the result of an action on the secretory structures. Klemperer has tried it in very many cases of profuse sweating in Professor Leyden's wards. The dose given was usually  $\frac{1}{6}$  gr. in pill, administered in the evening about 6 o'clock. If the action was insufficient, as many as five pills were given. In most cases the result was very satisfactory, even in those cases where atropin failed, and it was unaccompanied by any unpleasant symptoms.—*Therapeut. Monatshefte*, June, 1889; *The Practitioner*.

### CARBOLIC ACID IN WHOOPING-COUGH.

DR. ROBERT LEE wishes to emphasize the fact that the proper mode of administering carbolie acid in the treatment of whooping-cough is in the form of vapor, and by inhalation; and that the only way of effectively doing this is by boiling a solution of carbolie acid in water in the proportion of 1 to 1.5 per cent. When such a solution is boiled, the vapor is found to contain the acid in the same proportion—a fact not generally known. When used in the way referred to, carbolie acid is, in the opinion of Dr. Lee, the best remedy for the relief of the cough and other laryngeal symptoms.—*Brit. Med. Journal*.

### CLINICAL USES OF HYOSCINE.

MM. MAGNAN and LEFORT have been making some experiments with hyoscin prepared by Landenburg. This drug was first used in 1880, and since then MM. Gley and Rondeau have shown how it produces mydriasis and paresis in dogs, and Dr. Mitchell Bruce (*Practitioner*, xxxvii, 321) has pointed out its calmative effects clinically,

as well as the symptoms of failure of the heart and Cheyne-Stokes breathing that may be produced by doses as small as  $\frac{1}{60}$  gr. MM. Magnan and Lefort have found excellent results in five minutes from  $\frac{1}{60}$  gr. in acute mania. The patient loses his morbid activity and grows silent; then mydriasis and loss of power of accommodation come on, and he goes to sleep without further inconvenience for five or six hours—a better result than can be got from chloral or any other drug of the sort. It can be used in delirium tremens, in a child with severe local spasms, or as an injection of  $\frac{1}{20}$  gr. in the case of an hysterical woman with profuse sweating of hands and feet, which it will check for several hours. M. Laborde has found that, with perfectly pure hyoscin hydrochlorate, doses not more than a tenth part of what MM. Magnan and Lefort had used were quite sufficient.—*Progrès Méd.*

### EMMENAGOGUES AND PREGNANCY.

DR. L. ATTILL finds that, in his own experience, some of the so-called emmenagogues are practically devoid of special action upon the uterus. For many years he has made a practice of administering ergot to patients threatened with abortion, hæmorrhage being present but uterine action not having been excited. He finds that it checks hæmorrhage without exciting undue uterine contraction, and accordingly he does not hesitate to give it to pregnant women if for any reason it seems to be indicated. He has often administered ergot before labor in cases where there is a predisposition to post-partum hæmorrhage. In none of these cases has labor set in earlier than was expected, while in two or three cases it seemed to have been delayed. From personal experience he believes that iron, quinine and strychnine can be administered to pregnant women in ordinary doses with perfect safety.—*Brit. Med. Journal*.

### PEA REMOVED FROM AN EAR AFTER IT HAD BEEN THERE THIRTY-TWO YEARS.

DR. W. F. WRIGHT, of Leavenworth, reports the case of a woman, 40 years of age, from whose ear he recently removed a pea which had been there for thirty-two years. The patient herself, when a child, had introduced a pea in each ear, one of which was removed at the time. She suffered from vertigo nausea and loss of hearing in the ear which contained the pea. Since the removal of the pea hearing has been greatly improved and the other symptoms have disappeared.

### PREVENTION OF TYPHOID FEVER.

With reference to a circular recently issued by the Kentucky State Board of Health, in which attention is called to the increasing prevalence of

typhoid fever, and the advice given to boil all suspected water before using it, or to guard against contamination by using properly stored cistern water, the *New Orleans Medical and Surgical Journal* takes occasion to point out the immunity from this disease enjoyed by the citizens of New Orleans. The people of New Orleans of course use cistern water, not from choice but from necessity. The editor of the journal referred to says: "As typhoid fever is mainly disseminated by drinking water, we can feel confident that this horrible disease will never become a fruitful cause of deaths here as long as we adhere to our good and much-abused method of storing drinking water." It is not denied, however, that the water supply of New Orleans contains much organic matter and myriads of algæ. Our present authority also claims that having made a virtue of necessity in using open drains instead of sewers, and thereby escaping from the dangers of sewer gases within doors, New Orleans has at last awakened to the idea that "it is as good a city (for a large city) to live in as any in the Union, provided that the plainest laws of hygiene be obeyed."

#### THE TIME DURING WHICH ALKALOIDS REMAIN UNALTERED IN THE BODY.

This subject has been investigated by POLLACANI (*Deutsche Med. Zeit.*) who found that no trace of digitaline or santonine could be discovered after the lapse of four months, while atropine, daturine and physostigmine could be detected thirteen months after. Of codeine a trace was still present after the latter interval. Morphine and picrotoxine could be recognized after twenty-seven months, aconitine and cicutine after thirty-four months, and veratrine after thirty-nine months. Curarine appeared unaltered after twenty-eight months; after thirty-nine months the physiological test for this substance was ineffectual, although the characteristic chemical reaction could still be called forth. The author concludes from these experiments that the vegetable poisons are not so quickly destroyed by bodily putrefaction as has been hitherto supposed.—*Druggists' Circular*.

#### ANTIPIRYN.

The use of antipyrin is contra-indicated:

1. In all cases of cardiac weakness.
2. In diphtherial affections in which there is evidence of myocarditic lesion.
3. After exhaustive hæmorrhages.
4. During menstruation and dysmenorrhœa.
5. In catarrhal pneumonia generally, and in lobar pneumonia when there is œdema of the lungs—heart failure.
6. In the later stages of tuberculosis.

7. In all cases of great debility and exhaustion, and in the later stages of long continued fevers.

It is believed that the foregoing contra-indications with regard to the administration of antipyrin and similar medicaments will receive the approval of physicians generally.—HUMPHREYS, in *The Practitioner*.

#### ETHEREAL TINCTURE OF IRON IN CHRONIC NEPHRITIS.

DR. WYSS, of Geneva speaks very highly of the ethereal tincture of iron, or Bestucheff's tincture, as it is usually called on the continent, in cases of chronic Bright's disease. Five or ten drops of this preparation in a glass of water were given to a large number of patients from three to six times daily, the result being that in more than half of the cases the albumen entirely disappeared from the urine, and the œdema and other symptoms were also cured.

#### RESORCIN IN ECZEMA.

DR. UNNA strongly recommends in the treatment of seborrhœal eczema an application of linen cloths soaked in solution of resorcin. His formula is resorcin and glycerine of each 10, alcohol 180, mixed and diluted with 4 parts of water. In eczema with much secretion he applies a thin layer of cotton wadding soaked in the solution, which is then covered with some waterproof material, and kept in position with a bandage.

#### GURJUN OIL IN LEPROSY.

A systematic trial of the gurjun oil treatment, from which Father Damien and several members of his afflicted flock at Molokai are said to have derived benefit, is now being made at the leper hospital at Agra. Six typical cases have been selected, and the results are being closely watched by the medical officers of the hospital. Their report will be looked forward to with interest.

#### THE GLYCERINE TAMPON IN THE VOMITING OF PREGNANCY.

DR. S. B. KIRKPATRICK blistered the cervix in an obstinate case of vomiting in a pregnant patient, and observing that the patient was not relieved until the serum was formed and discharged, conceived the idea of procuring a watery discharge by the use of glycerine. He accordingly inserted into the vagina a tampon saturated with glycerine. The distressing symptom was at once removed and, on its return at intervals, was always relieved by the glycerine tampon.—*Texas Com. Rec.*

## SOCIETY PROCEEDINGS.

## Medical Society of Virginia.

FIRST DAY—TUESDAY, SEPT. 3, 1889.

The twentieth annual session of the Medical Society of Virginia convened in Roanoke, Va., at 8 P.M. Tuesday, September 3, 1889, the President, Dr. E. W. Row, of Orange, Va., in the chair. The address of welcome was delivered by Dr. A. Z. Koiner, chairman of the local committee of arrangements; Dr. Thomas J. Moore, of Richmond, Va., delivered the annual address, selecting as his subject, *Man and His Development*.

SECOND DAY—WEDNESDAY, SEPT. 4.

DR. JOHN A. WYETH, of New York, read a paper on

## THE STATUS OF COCAINE IN SURGERY.

After a note or two on the history of cocaine as a surgical anæsthetic, in which he accords to Dr. Karl Koller, of New York City, the credit due for its introduction in eye surgery, and to Dr. J. Leonard Corning, of New York City, the credit for its practical application to other surgical purposes than anesthesia for eye surgery, he remarked first upon its dangers, due to idiosyncrasy, etc. Its dosage is uncertain, differing widely not only in different individuals, but in the same individual at different times. The general rule should be to begin with the minimum dose, gradually increasing it, always watching the pulse, face, respiration and pupil. In small doses it increases the number of respirations and is a cardiac stimulant; in large doses it arrests the heart in diastole and the action of the respiratory muscles. Cocaine is never applicable to children under 10 or 12 years of age. In his several hundred applications in adults, in all parts of the body, he has several times observed pallor of the face and fainting, but due, most probably, to the patients being overcome by the sight of blood, etc. In some, however, it was due to absorption of the drug. Exhilaration is not an uncommon symptom, and in rare cases it increases to boisterousness. In one instance convulsive movements occurred, episthotonos being rather well marked. In another case a convulsion occurred fourteen hours after a gradual injection of 30 minims of a 4 per cent. solution of cocaine (gr. jss). In many cases, when not applied about the eye, dilatation of the pupil occurs, indicating absorption by the blood. For hypodermic purposes he uses 20 grains of cocaine and 3 grains of boric acid, dissolved in an ounce of distilled water—approximately a 4 per cent. solution. A stronger aseptic solution is equal parts of distilled water and saturated solu-

tion of salicylic acid. Always dissolve cocaine in water free from lime.

Following these general considerations Dr. Wyeth gave interesting specific directions for the employment of cocaine in various operations of minor surgery, including amputation of the fingers, incision of felons, removal of finger nails and tumors, and operations about the eye, mouth, nose, urethra, anus, scrotum, etc.

DR. HUNTER MCGUIRE, of Richmond, Va., said that he did not think that Dr. Wyeth had dwelt sufficiently on the dangers of cocaine. He had used this remarkable agent almost every day for the past five years, but he had come very near killing one or two patients with it—so uncertain is its paralyzing effect in some cases, which cases cannot be foretold until the danger is recognized to be at hand. He had read that Dr. Sims had injected a few minims of a 20 per cent. solution of cocaine muriate into the male urethra, and in twenty minutes his patient was dead. Dr. McGuire said that he had cocaineized a great many children without observing the very serious effects referred to by Dr. Wyeth; in fact they seem to stand cocaine as they do chloroform anesthesia—very well. But there are objections to cocaine. Undoubtedly it interferes with the repair of wounds by the first intention. Another thing—during the session of this society two years ago, in Richmond, he heard a distinguished authority in such matters, then a resident of New York City, affirm that a cocaine habit, in the sense in which the term habit is applied to the whisky habit, the morphia habit, etc., could not be established. But he is certain he has seen a case or two of the *cocaine habit* in patients who have come under his care.

DR. WYETH remarked, in reply, that he endorsed everything that Dr. McGuire had said—in fact the dangers of the indiscriminate use of cocaine are very considerable. He did not mean to imply the idea in his paper that the danger of cocaine, when used with children, was in the drug itself, but in the imperfect manner in which it is generally administered to them, because of their struggling to resist its administration, and the peculiar sensation, or loss of sensation, in the part which frightens them.

## MEDICAL REFORMS, WITH SPECIAL REFERENCE TO THE PROFESSION OF VIRGINIA.

was the subject of the address by the President, DR. E. W. ROW, of Orange, Va. He advocated the establishment of a State General Hospital, to be sustained by the State, just as are the asylums; that matters of professional interest connected with the management of such an institution should be placed under the control or direction of the Medical Society of Virginia. In other words, he thought that the medical affairs of the State should be directed by the medical men of the

commonwealth, just as are the legal affairs by the legal men, etc. The medical profession has shown its ability to manage such matters as belong to it, as evidenced by the excellent work done by the Medical Examining Board of Virginia—the creature of this society. The insane hospitals and like institutions should be more directly under the supervision of this society, so far as the medical affairs connected with them are concerned. It is the duty of this society at this time to put itself to work to secure for the State Board of Health an annual appropriation from the State sufficient to pay all of its necessary expenses, it appearing that the law establishing the Board, some seventeen years ago, being altogether satisfactory, with the exception that the law very foolishly concludes with some such proviso as, “provided the said Board of Health shall not be an expense upon the State.”

The next order of business was the discussion of the selected subject,

#### CROUPOUS PNEUMONIA.

The appointed leader, DR. B. L. WINSTON, of Hanover, Va., stated that he would confine his remarks to uncomplicated cases of the disease. The *diagnosis* is not difficult, although sometimes the disease escapes detection unless resort is had to the physical signs. Pain is probably never present unless more or less pleurisy complicates the pneumonia. Rusty colored sputa, though pathognomonic when seen, does not by any means occur in the majority of cases, according to his experience; and on this point he thinks the text-books should be corrected. The *causes* may be classed as either specific, exciting, or predisposing. The view that pneumonia is due to a specific organism does not meet with common approval. Dr. Winston thinks that pneumonia is not simply a local inflammation of the lung, but that this is but an expression of a general disease, and that the pneumonia deserves no higher classification than the intestinal ulcers of typhoid fever. Croupous pneumonia is not produced by extension of inflammation, but in such cases lobular pneumonia is the result. It is not produced by inhaling irritating gases, nor by traumatism, nor by “cold,” as are other inflammations of the air passages. It is a self-limited disease and frequently occurs as an epidemic. The common asthmatic tendency cannot be due to the height of the fever, nor to cardiac weakness, nor to the amount of lung consolidated (for the amount invaded is often very small). It is, at least, certain that the cardiac failure in no way corresponds with the severity of the other symptoms. It seems to the speaker that the tendency to heart failure, which is the most alarming symptom in uncomplicated cases, is due to a morbid agent acting on the nerve centres. But the exact cause of croupous pneumonia is a sub-

ject for further investigation. The germ theory may or may not be true. The *predisposing* causes are age (under 60), the male sex, the negro race, certain diseases, as typhoid fever, winter and spring seasons, etc. The *exciting* causes are, in general, such things as tend to lower the vital powers, as exposure to inclement weather, insufficient clothing, neglecting the wearing of flannel winter and spring, etc. It is more common south than north, pneumonia being almost unknown in the frigid zone. During the winter and spring almost every article of food has the stamp of age upon it, and it seems more probable that the character of the food then taken, when the vital powers are at their lowest, contribute most largely to the development of the disease. As to *treatment*, most every drug has been tried; yet the mortality among adults is second only to that from consumption. Maraylionia abstracts from five to ten ounces of blood on the fourth or fifth day, when the heart is on the eve of being overpowered by the pneumonic toxic matter; but Dr. Winston thinks stronger evidence needed to justify resort to such bleeding on such occasions, although there may be occasionally times when some venesection is useful. He also thinks large blisters of doubtful propriety, although he has seen blisters relieve pain. Calomel has no place in the treatment of croupous pneumonia; aconite in the commencement, and quinine, given early as an abortive, may be useful; but he has gotten the best results when he has given the least medicine. Hot poultices, opium to relieve pain, stimulants when needed, food, hygienic measures, and, above all, skillful nursing, will be all that can be done in uncomplicated cases.

DR. H. C. BECKETT, of Scottsburg, Va., also read a paper on the subject. The specific cause of croupous pneumonia is undetermined. No age has either a notable proclivity to the disease, nor is any age exempt. It is perhaps most frequent between the ages of 20 and 40, and after 60. In adult life it occurs in males three times as often as in females; in females it occurs most frequently at the catamenial periods. Outdoor laborers are more liable than indoor workers. Habitual alcoholic drinkers, malarial subjects, convalescents from severe acute diseases, etc., are most liable to the disease. Erysipelas, measles, diphtheria, small-pox, etc., are predisposing causes. Traumatism, especially in the aged, a previous attack of pneumonia, are also predisposing causes. It often prevails as an epidemic in the mountainous regions of the South. The first five months of the year are its season. Thus it is seen that all things predispose to pneumonia that depress vital action. Dr. Shaw, of St. Louis, believes that perturbations of the vaso-motor centre in the medulla causes pneumonia by impressions conveyed through nerves connecting this centre with the stomach. As to *treatment*, use stimulants or

depressants, as required. If both lungs are involved, so as to leave little breathing surface, bleed. In such cases venesection affords immediate and remarkable relief. Large hot poultices over the lungs reduce blood pressure, while the heat stimulates the heart. Aconite is preferable to veratrum; but he prefers antifebrin as the antipyretic, to be followed by quinia, which latter he considers the sheet anchor in pneumonia. He usually prescribes 5 grains every four hours until the fever breaks. In the second and third stages he generally combines ammonia, carbonate and digitalis. The early exhibition of a large dose of calomel is useful. Opium is useful to allay pain and restlessness. Expectorants have no place in the treatment of pneumonia. Blisters at the beginning of the third stage hasten resolution. Alcohol is essential as a food and to sustain the heart. Many believe that the disease is contagious, and that four days is the period of incubation.

DR. LEWIS G. PEDIGO, of Roanoke, Va., read a paper entitled,

SEDATIVE DOSES OF CALOMEL IN ACUTE CROUP-  
OUS PNEUMONIA.

He stated that the title of his paper referred to doses of 30 grains and upwards. He gave a history of the use of this treatment in various acute diseases by a few members of the profession for years past, and then explained the method of administering the drug in this treatment. He reviewed the condition of the secretions and the various indications of treatment in pneumonia, gave a systematic and detailed account of the numerous and apparently diverse effects of the large doses of calomel, classified these effects, and showed how they were all dependent on two general principles, namely, stimulation of the secretions, and sedative influence on the nerves. He argued the adaptability of these effects to the chief indications in pneumonia. The entire paper was based on clinical experiences, and one case was briefly reported to illustrate the treatment advocated. The important effects claimed were the promotion of the salivary, gastric, hepatic and intestinal secretions, and unloading of the portal circulation (followed by improved digestion and assimilation), increased and improved action of the kidneys and skin, loosening of the bronchial and pulmonary secretions, relief of cough, lowering of temperature, and promotion of sleep.

Honorary Fellow, DR. BEDFORD BROWN, of Alexandria, Va., gave a

RÉSUMÉ OF HIS PERSONAL EXPERIENCE OF FOR-  
TY-ONE YEARS IN THE TREATMENT OF  
CROUPOUS PNEUMONIA.

During this period of time, he has seen four or five different methods of treatment adopted and practiced, and finally discarded. First, as to the

depletory plan, at first it was used in every case; then only in certain cases, and finally it was entirely discarded. Then came the mercurial plan, in which calomel in small doses, with Dover's powder, with mercurial inunction, were used until ptyalism occurred. The great majority of cases recovered under this treatment. Then followed the sedative treatment, consisting of the use of veratrum viride, aconite, and ultimately digitalis. The sedative treatment of Norwood gave birth to all of our subsequent ideas of sedation. This was an advance on the pure depletory treatment, and resulted in real good. Then again came the stimulant treatment. This was a still further advance, and has brought more and better fruits than any other single treatment. While this also may be modified and combined with elements of other treatments with advantage. Dr. Brown has not derived benefit from the pure antipyretic treatment. He has, in former years, seen much of the epidemic form of typhoid pneumonia, with a tendency to collapse which was constant and great. In this form he has used large quantities of whisky—a quart per diem—carbonate of ammonia, tincture of nux vomica, and chloroform internally. In this form he has also used, in connection with stimulants, solution of the acetate of ammonia, tincture of nux vomica, tincture of chloride of iron, with benefit. Dr. Brown does not think, from his long experience, that adherence to any one single routine treatment exclusively will give as good results as the mixed treatment, combining some of the good features of all; but never forget the value of stimulants and nourishment. He has seen cases of pneumonia with slight fever, slow pulse, moderately excited respiration, etc., recover without medication.

DR. J. H. NEFF, of Harrisonburg, Va., said that croupous pneumonia is a disease of specific origin, running a regular course; but no one knows the exact character of this poison. He has always believed that it was not a purely local disease, but a systemic disease of specific origin, having its local manifestation in the inflammation of the lung. It prevails mostly in populous districts, especially as one approaches the tropics. He agrees with Dr. Winston as to the exciting causes. The predisposing causes are to be found in the constitution of the patient and season of the year. The disease being of a specific character, must run its course, and therefore he has had no faith in any abortive plan of treatment. A great many cases run their course to recovery without any treatment whatever, other than the ordinary attentions of humanity. He has seen antipyrin do just as much in curing pneumonia as calomel. In children, he always uses a light flannel jacket, lined inside with oil silk. He never gives a dose of calomel now. He does not condemn the use of aconite or veratrum viride;

but he finds good diet, etc., a much better class of remedies. It is of the first importance to sustain the strength of the patient, and especially his heart.

Fraternal Delegate, DR. J. G. WILTSHIRE, of Baltimore, Md., said that studying the subject of croupous pneumonia after Lépine, Sévestre, Charcot, etc., one must accept the theory that it finds its origin in a specific pathogenic germ; yet it cannot be denied that there are certain meteorological conditions that stand in a strong causative relation to its production—it occurring more frequently in low temperature—one acting as a specific, the other as an exciting cause. We are constantly exposed to the invasion of the pneumococci; but for the want of the necessary conditions to render the mucous membrane of the lung a suitable soil for their culture and growth, it is able to resist them for a time, only to yield when such exciting causes as cold and traumatism supplement the specific influence of the germ. Apropos of the theory that the pneumococci have other habitats than the lungs, he called attention to the study of Sévestre of an epidemic of broncho pneumonia, complicating cholera infantum and other enteric troubles, in which he found the microbes of pneumonia in the intestinal tract, whence they were carried to the lungs by the lymph channels. The treatment of croupous pneumonia calls for heart sedatives, heat and moisture in the form of hot cloths; these, if used in the first stage, may abort the disease. Should it, however, pass into the stage of red hepatization, a supporting and stimulating plan should take the place of sedative one. Watch the temperature and heart as closely as the powers of the patient. Alcohol is important in the second and third stages. Quinine and antipyrin, when used together, are the best antipyretics. They not only reduce the temperature, but preserve the powers of the heart. Carbonate of ammonia does the twofold work of aiding in liquefying and expectorating the fibrinous deposit, and keeping the heart's force up.

DR. HENRY M. PATTERSON, of Staunton, Va., remarked that if this is a specific disease, the treatment given has certainly been at variance with this idea. He does not believe that it is simple hyperæmia of the lung. The gravity of the attack depends on the amount of exudation. How to remove the engorgement is the question. At this period is the time to abort the disease if possible. He may be ranked as behind the times; but his success with the lancet now is just as good as it was when he began practice in 1851; and that success is just as good as is that by other plans of treatment now in vogue. He gives alcohol in the second stage in almost every case, both for its food and stimulant qualities. He has had some remarkably satisfactory results from ergot.

DR. HENRY V. GRAY, of Roanoke, Va., said that the important question is, What produces the great depression of the system in cases of croupous pneumonia? If due to exudation in the alveoli, that condition needs prompt attention.

DR. GEORGE TUCKER HARRISON, of New York, N. Y., read an elaborate Memoir of the late Dr. James L. Cabell, of the University of Virginia, which was ordered to be incorporated in the Report of the Neurological Committee.

DR. E. T. BRADY, of the Southwestern Lunatic Asylum, at Marion, Va., read a paper entitled:

#### MENTAL ACTION—MATERIAL ACTION.

The Doctor stated that he would treat the title as a fact considering it established by the following three propositions:

1. That mental impressions involuntarily originate physical action, and that material impressions give rise to this involuntary mental action.
2. That loss of cerebral substance is followed by loss of physical or expressional function, and that disuse of mental function is followed by a corresponding atrophy of cerebral substance.
3. That abnormalities of organic function, have as their sequence, abnormal ideation.

He devoted his paper to the support of these propositions. In support of the first proposition, he cited the phenomena of sweating, nausea and vomiting from fright—the quickened circulation and blushing of the lover or of wounded modesty, the flow of tears and gestures of grief, joy, etc., changes in expression and movement, in a dreaming sleeper, consciousness of the presence of a limb, as evidenced by sensations referred to a limb after amputation, claiming that such sensations are not imaginary, but the outward projection of a previously stored impression; also claiming that all reflex action is evidence of material impression as the cause of mental action.

In support of the second proposition, he presented the records, clinical and post-mortem, of several cases, and cited the advances in cerebral localization and microscopic pathology. He incidentally recommended the adoption of vivisectional experimentation as the means of executing the death penalty upon criminals. In support of the third proposition, he referred to what had been advanced under the other headings, calling attention to the gradual and simultaneous decline of the cerebral and mental powers in diseases of the brain and cord.

The *Report on Materia Medica and Therapeutics* was presented by DR. WILLIAM E. COOPER, of Woodville, Va. From the phenol group comes *Phenactine-Bayer*, a tasteless powder, freely soluble in alcohol, less so in glycerin, and still less so in water. It is a non-toxic, reliable, antipyretic and antineuralgic. The usual dose of 7.5 grains lowers the temperature from 1.8° to 3.6° F. for hours. It is best given in powders or soluble

pills. *Sulfonal-Bayer* promptly causes natural sleep in from half an hour to two hours of several hours' duration, in doses of 15 to 45 grains. It does not act unfavorably upon the heart, respiration, temperature or digestion. It creates no desire to increase the dose. It is given in a wafer, or it may be dissolved in soup or tea. *Amylene hydrate*, an isomer of amylic alcohol, is physiologically ranked between chloral and paraldehyde. It is a colorless, slightly oily liquid, boils at 102.5° C.; sp. gr. 0.81. It is freely soluble in alcohol, but requires eight parts of water. It is given with extract of licorice, or in red wine and sugar. In doses of from 50 to 75 grains it causes neither nausea, headache, indigestion, nor other unpleasant after effect; but more frequently than other hypnotics, it induces refreshing sleep. *Methylal* is a new hypnotic, is soluble in water, rapidly eliminated, and leaves no ill effects. Dose 3 to 5 grams. *Salufer* (neutral sodium silicofluoride), requires 1 ounce of water to dissolve 2½ grains, it is a powerful unirritating surgical antiseptic. For ordinary uses a grain is dissolved in an ounce of water to syringe out cavities, etc. It corrodes steel, but does not affect sponges. *Guaiacol*, an ether, derived from beechwood creosote, is a colorless liquid, of aromatic odor, slightly soluble in water, but readily so in alcohol and fixed oils. It is used by inhalations or in doses of a half to one minim, several times daily in consumption. The solution should be kept in colored bottles.

### THIRD DAY—THURSDAY, SEPTEMBER 5.

DR. R. S. MARTIN, reporter on Section of Obstetrics and Diseases of Women and Children, read a paper on

#### ADVANCES OF DISEASES OF WOMEN.

Massage (Brandt's method) is reported to be practised with great success by Dr. Boldt, of New York, in the following conditions: Chronic and subacute para- and peri-metritis; all non-acute inflammatory uterine diseases; chronic and subacute oöphoritis; catarrhal salpingitis; all uterine displacements, with or without adhesions, unless dilated tubes are present; rectocele and cystocele; uterine hæmorrhages, not dependent on neoplasms; incontinence of urine dependent on relaxation of the visceral sphincter; hæmatocele; floating kidney, and prolapsus recti. It is contra-indicated, according to some, in all acute inflammatory processes; dilated tubes, and in all conditions where suppuration is suspected. This treatment is not useful in patients with very fat abdominal walls. The sèances vary from three minutes to a quarter of an hour.

Dr. Martin exhibited a *Outerbridge dilator*—an ingenious instrument, which acts also as a drainage tube. In sterility dependent on stenosis this introduced five or six days before menstruation

into the contracted cervix uteri and allowed to remain. It is also of value in sterility, due to flexions. For full description see *Medical Record*, April 20, 1889. *Electricity* holds a high place in the treatment of carefully selected cases. Engelmann uses galvanism for inflammatory products which admit of restitution, indurations, deposits due to interstitial inflammation, certain neoplasms. Davis, of Birmingham, Ala., uses faradisms for subinvolved uteri. It is useful in many cases of retroversion, many so-called pelvic inflammations, in amenorrhœa due to atrophy of the uterus, and in menorrhœa due to relaxation of the muscles. Many think electricity, after Apostoli's method, important for uterine fibroids; but the dangers of sepsis must be guarded against. Some think electrolysis of fibroids uncertain.

For *carcinoma uteri* Brown uses the curette freely and applies, on a tampon, a saturated solution of zinc chloride. Mundé uses a weak solution of sesquichloride of iron. Schramm injects half to one grain in an ounce solution of corrosive sublimate into the diseased mass two or three times a week, causing cessation of fetor and purulent discharges, and lessening the frequency of hæmorrhages. The feeble absorptive power of the degenerated tissue offers immunity from mercurial poisoning. The following is an antiseptic and sedative suppository extensively used in Paris:

R.	Iodoformi . . . . .	gr. xv.
	Camphoræ . . . . .	gr. jv.
	Ext. belladonnæ . . . . .	gr. j.
	Ol. theobromæ . . . . .	q. s.
℞	Make one suppository.	
S.	Put high up in vagina at night.	

High amputation of the cervix is advisable if the disease has not passed beyond the internal os. If disease has not extended beyond the uterus, hysterectomy is advised. As to *uterine fibroids*, Coe scrapes away the hypertrophied mucosa. *Vaginal hysterectomy* has been done successfully. During 1888, abdominal hysterectomy was done 43 times with only 9 deaths. *Uterine anteversions and flexions* are but rarely congenital, but results of previous para-metritis. Use antisepticized laminaria tents to soften the tissue, and render intra-uterine treatment more thorough. Use preliminary course of hot douches and glycerine tampons, then straighten the uterus bimannually, and hold in place by a pessary or intra-uterine stem. Dilatation with bougies and the persistent use of hot water, will usually effect a cure. Goodell advocates thorough dilatation with steel branched dilators, when dysmenorrhœa is a prominent symptom. Wylie condemns pessaries, but dilates rapidly under thorough antiseptis. *Alexander's operation* for shortening the round ligament has grown in favor. Mundé reports 23 cases with excellent results. Kellogg reports 65 successes out of 69 operations.

Schucking has devised and practiced successfully *vaginal suture of the uterus* in 18 cases for radical cure of retroflexed or prolapsed uterus. Hysterorrhaphy finds favor in Germany, where prejudice exists against Alexander's operation. A case of *lacerated cervix* operated on by the reporter in May, 1886, was delivered of twins, each weighing eight pounds, in July, 1889, without further laceration. Herrick pares the lips and holds them in apposition, not by sutures, but by an elastic band shaped like the cervix, large enough to cover the whole os and cervix, with a small hole in the band to allow the secretions to pass. Dr. T. Gaillard Thomas does not claim that operations for diseases of women are especially liable to *insanity*, but mentions six very significant cases, in none of which were the kidneys at fault, nor could the sequel be charged to iodoform poisoning.

#### REPORT ON ADVANCES IN OBSTETRICS.

The reporter, DR. CHAS. W. PRITCHETT, of Keeling, Va., first spoke of *Vomiting of Pregnancy*. Hewitt analyzes fifty selected cases, and contends that these cases confirm his opinions; that the vomiting of pregnancy is in most all cases associated with and dependent on uterine displacement, and thickening or induration of the cervix. Gill Wylie attributes it largely to induration of the cervix. Jaggard ascribes it to endometritis gravidarum. *Treatment*.—Gunther, of Montreaux, advises galvanism. Green reports cases cured by chloride of sodium. Collins and William Duncan report cases cured by the application of 10 per cent. solution of cocaine to the vagina and cervix. Rose recommends rectal injection of carbonic acid. *Anæsthetics*.—Recent writers accord antipyrin a very high place in the first stage of labor—relieving pain and fatigue while the uterine contractions are not interfered with. Chloroform holds its own in the second stage of labor. Budin advises chloroform only to dull pain and not to complete anesthesia, unless to perform an operation more severe than the application of the forceps. Swieicki, of Posen, has used a mixture of nitrous oxide and oxygen in the proportion of 4 to 1. Winckel regards the mixture as harmless and especially useful in cases of elderly primipare. Hypnotism is a failure as an obstetric anæsthetic. *Antiseptics*.—The comparative results in hospitals in which antiseptics are used and of those in which they are not, are sufficient to show their great value in reducing the mortality of the lying-in chamber. Corrosive sublimate in weak solutions and in skilful hands is still the queen of antiseptics and germicides. *Eclampsia*.—There is yet considerable discord as to the cause and treatment of puerperal convulsions. Santos believes that the albuminuria is the result of reflex irritation of the sympathetic and renal nerves by the enlargement and, later

on, the contraction and retraction of the uterus. Lusk says albuminuria is caused by renal insufficiency, and is not the cause of the convulsions. Paget denies the dependence of eclampsia on albuminuria, but attributes it to a reflex cause. *Mastitis*.—According to Richardson this is the result of septic infection, and he urges that the child's mouth be kept perfectly clean and the nipple well washed with antiseptics. Monti advises that the fissures of the nipple be painted with a solution of gutta-percha in chloroform. *Puerperal septicæmia*.—It is disputed whether this disease is dependent on one or more organisms. Vidal claims that there are at least two, and that there is no characteristic difference between the germs of puerperal septicæmia and erysipelas. Gussow denies their identity and insists that erysipelas cannot cause puerperal septicæmia. Doyon says they are one and the same. Others assert that puerperal septicæmia is of an erysipelatous nature and the fever typical of erysipelas.

#### REPORT ON ADVANCES IN DISEASES OF CHILDREN.

The reporter, DR. A. S. PRIDDY, of Keysville, Va., has not found any material advance except in diseases of the alimentary canal. The researches of Holt, Escherich and others with reference to *intestinal bacteria* were summarized with the deduction that three facts must be kept in mind in studying the effects of microorganisms upon the human system: the nature of the organisms, the dose and numbers in which they enter, and the susceptibility of the patient. The two varieties of bacteria which have been isolated and studied in the intestines of young children are the bacterium lactis aerogenes (found in the upper portion of the small intestine), and the bacterium coli commune. The first decomposes milk sugar, with the development of lactic or acetic acid, to which the acidity of the intestine is due. After a full review of the subjects involved, the lessons are drawn that the infant must not be overfed, and that the milk (in bottle-fed cases) should be sterilized, and the vessels themselves that hold the milk should also be sterilized. *Milk was first sterilized for food* in Munich, 1886. Dr. Caillé, of New York, introduced sterilized milk as an artificial food into this country in 1888, and the results have been favorably received. It remains sweet for six weeks, while boiled milk can be kept only four or five days even on ice. *Stomach washing* for gastro-intestinal disease, first used in Prague in 1880, satisfactorily introduced by Seibert in New York in 1888, is especially serviceable in dyspeptic disorders attended with regurgitation of food, in cholera infantum, etc. Pass a long, soft, velvet-eyed rubber catheter attached to a fountain syringe, through the pharynx into the stomach; pour in a cupful of warm water, while the child is in the upright position. Then tilt the child forwards, and the water returns

through the catheter. For *intestinal irrigation*, pass a Nélaton soft rubber catheter (with a hole in the end instead of at the side) some 8 or 10 inches into the bowel. Through this catheter, attached to a fountain syringe, pass a quart or two of warm water containing 1 drachm of sodium salicylate to the pint of water. Though the treatment is not new, it is only during the past two years that it has become popular in this country—chiefly through the reports of Dr. Booker, of Dr. H. P. Wilson's Sanitarium, of Baltimore. It is useful in dysentery, gastro-enteric catarrh, acute and follicular enteritis, etc. Dr. Priddy has used the treatment successfully in a number of cases of gastro-enteric catarrh, dysentery, etc., relieving the nausea, vomiting, tenesmus, etc., and curing his patients.

Honorary Fellow, DR. GEORGE TUCKER HARRISON, of New York, read

A FURTHER CONTRIBUTION TO THE STUDY OF  
THE ETIOLOGY AND PROPHYLAXIS OF  
PUERPERAL SEPTIC INFECTION.

The doctrine of auto-infection, which has recently been brought into great prominence, and the industrious researches of the bacteriologists, with the practical deductions from them, have divided obstetricians into two parties diametrically opposed to each other. The one side attaches all importance to the disinfection of the obstetrician (Mermann's subjective infection); the other regards it as a matter of necessity to subject the parturient woman, in a greater or less degree, to antiseptic measures (objective antiseptis). The writer took the ground of those who advocate the paramount importance of subjective antiseptis, in the paper read before this society in 1885, and has had no reason to change his ground. Of course this position does not exclude the thorough cleansing and disinfection of the external genitals. The views of Kaltenbach were quoted, who insists upon it that an obstetrician, even with clean hands, can induce infectious forms of disease. He believes that, as the surgeon disinfects his field of operation, so must the obstetrician disinfect the parturient canal, as well as the vicinity. Winter (*Zeitschrift f. Gyn.*, etc.), as the result of bacterial investigation, draws the inference that it is necessary to disinfect the cervix and vagina to avoid auto-infection. Steffek and Dolderlein arrive at the same conclusion. The writer believes that if the demands made by the bacteriologists should be generally acceded to, and it should become a universally accepted rule of practice that the cervix and vagina of every parturient woman should be subjected to thorough and energetic disinfection, an immense amount of injury would be inflicted. These disinfective procedures deprive the vagina of its physiological mucus, and render it more vulnerable. It becomes more liable to the attack of in-

fective germs. Moreover, labor is mechanically retarded when the vagina lacks its normal mucus, nor must it be left out of mind that disinfection of the vagina and cervix is a painful manipulation. Probably the most serious objection which can be urged against the auto-infection doctrine is that it diminishes the personal responsibility of the obstetrician, and that wholesome dread of infection disappears, which every one should have who examines a parturient woman. The distinction was made between septic infection and putrid intoxication. Cases of so-called auto-infection are really cases of ptomaine intoxication. The microorganisms of septic infection are streptococci. According to Bumm, the streptococci of erysipelas and phlegmonous inflammations are identical. Bumm's careful and exact bacteriological studies lend no countenance to the doctrine of auto-infection. Leopold's clinical experience is very striking. Of 150 women treated without vaginal douches, only nine had slight febrile phenomena. When the cervix and vagina were disinfected, there was a marked rise of morbidity. The doctrine of auto-infection is a retrograde movement, and tends to imperil our present attainments in the prophylaxis of septic infection.

(To be concluded.)

### LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

*Tetanus as an Infectious Disease—The Scottish System of Admitting Voluntary Patients into Lunatic Asylums—The Microscopic Examination of Urinary Deposits—The Antiseptic Power of Hydro-naphthol—Miscellaneous Notes.*

Tetanus as an infectious disease is now attracting a great deal of attention. At a recent medical meeting a member dwelt upon the virulence of the soil when contaminated by the dejections of tetanic horses. He insisted upon the frequency of tetanus in wounds of the lower extremities. Thus, in Havana, it was stated, out of 162 patients suffering from tetanus 132 had contracted it from wounds of the legs and feet. The disease is frequent in persons who after being wounded get in contact with the soil, as in the cases of comminuted fracture, in which the bones are forced into the ground, and crushing of the bare feet, also when the injury is inflicted with an agricultural instrument. Experiments made with pure soil and with a soil known to be impregnated strongly support this view. Certain soils seem to preserve their virulence much longer than others, and stagnant water has been found to favor the proliferation of the microbe.

The Scottish system of admitting voluntary patients into lunatic asylums appears to work very satisfactorily. Last year the number of such patients was fifty-five. They are described as persons whose mental condition is not such as to render it legal to grant certificates in their case, yet they are necessarily sufferers who are sufficiently conscious of their own condition to feel the need of restraint. Unlike our habitual drunkards who place themselves in "Retreats," they cannot be detained for more than three days after giving notice to leave if they persist in that desire, and it appears that they are not registered as lunatics. At the visits of the Medical Commissioners to asylums all voluntary inmates are seen, and they have then an opportunity of making statements in regard to their position. Where there is reason to suppose that they fail to understand the conditions of their residence, it becomes the duty of the official visitors to explain. The Scottish Commissioners in Lunacy state that for some years past nothing has occurred to shake their faith in the advantages of the system or of the law under which it is regulated.

A good suggestion has been made with regard to the microscopic examination of urinary deposits. In order to examine these deposits, it is necessary to allow the liquid to remain quiet for some time. In hot weather the urine is liable to undergo decomposition during this time, and to avoid this it is proposed to add a solution of boric acid and borax. This solution is obtained by adding to a 12 per cent. solution of borax another 12 per cent. of boric acid and filtering while the liquid is warm. To the urine to be preserved about one-fifth to one-third of its volume of the boracic solution is added, which enables the deposit to be collected before any decomposition sets in.

Mr. A. H. Mason has recently been making experiments upon the antiseptic power of hydronaphthol and finds it to be about fourteen times as strong as carbolic acid, and in fact, out of thirteen substances of this class only one, corrosive sublimate, was found to surpass it. He found that as an antiseptic hydronaphthol, when dissolved in ordinary water, was not more than half as powerful as corrosive sublimate when dissolved in distilled water, but under such circumstances as the surgeon meets with it is said to be more effective than sublimate. As a germicide he considers it to be at least as powerful as corrosive sublimate for anthrax and more so for bacillus subtilis, even when the latter was being used under conditions most advantageous to it.

An interesting communication has been made to *The Lancet* by Dr. A. H. Hassall, the salient point of which consists in the suggestion that all phthisical patients should be provided with spittoons containing perchloride of mercury solution for the reception of the sputa, whilst the use of

cloths or handkerchiefs for this purpose should be discouraged.

Dr. Drysdale has had under his observation a case where a man who had previously been in robust health, and of a healthy family, married a woman in 1886 who had suffered from hæmoptysis three years before her marriage, and who died of phthisis pulmonalis. The husband had the first symptoms of the disease in 1887, a year after marriage, and is at present suffering from chronic phthisis. Dr. Drysdale contributes this case to the discussion now going on as to the part played by contagion in the spread of tuberculosis. Many statistical facts point in the direction of such contagion. Thus the disease is absent in Alpine districts, thinly inhabited by a healthy population, and it is most prevalent where people are most crowded in large houses with flats, as in Paris and Vienna.

At the General Infirmary, Leeds, the practice is commonly adopted of washing out the peritoneum after abdominal section, in which blood or other fluids have been effused. The fluid, whether simple warm water or boracic lotion, is usually poured into the wound from a jug, being introduced into the cavity by means of a glass funnel attached to a glass drainage tube by about 2 feet of rubber tubing. The drainage tube is introduced deep in the pelvis, by which means the water enters exactly where it is wanted and washes upwards and out of the abdominal wound all blood clots or effused fluids. The drainage tube is left *in situ* after by pressure removing as much of the fluid as possible.

Some recent statistics of sleep, though they may not prove anything of importance, are interesting. Students sleep longer and are less tired than other men. The time needed to fall asleep is about the same in all three classes—20.8 minutes for the men, 17.1 minutes for students, and 21.2 minutes for women. In each case, however, it takes longer for those who are frequent dreamers and light sleepers to fall asleep than persons of opposite characteristics.

Sir Morell Mackenzie has been presented with the freedom of the city of San Remo, richly illuminated and enclosed in an elegant casket, in recognition of his patronage of that city. This act of appreciation, suggested by Mr. Squire, of San Remo, was warmly responded to by the Mayor and the inhabitants.

Within the last few weeks thirteen patients from various parts of the country have been sent to Paris at the expense of the Lord Mayor's Fund for treatment at the Pasteur Institute. All are suffering from bites of dogs supposed to be rabid.

## DOMESTIC CORRESPONDENCE.

**A Nosological Problem.**

*To the Editor:*—Will you kindly publish the history of the following case, allowing me to ask through the columns of *THE JOURNAL* a solution of what seems to me an incomprehensible nosological problem.

Ethel J., aged 8, the daughter of healthy parents, has never had any lingering or serious illness; digestion fairly good, bowels very inactive, appetite good, though capricious, sleeps well, subject to quite frequent attacks of headache. On the evening of August 20, shortly after supper, was seized with an attack of nausea and vomiting. The ejected matter consisted of partially digested food and a membranous substance of an irregular shape, six inches in length by five inches in width. On one side here and there were little lumps of fatty matter the size of a small pea.

I have never in practice or in literature met with anything like it, and would be pleased to learn if any of the readers of *THE JOURNAL* have.

C. M. FERRO, M.D.

Tracy, Minn.

**The New Official Register of Physicians.**

*To the Editor:*—Will you have the kindness to notice in your columns for the benefit of your numerous subscribers in Illinois, that this State Board of Health has in preparation a new Official Register of Physicians and Midwives, and suggest that those who have changed their place of residence or removed to other towns since February, 1886, should notify the Secretary at Springfield of such change of address without delay.

JOHN H. RAUCH,

Secretary Illinois State Board of Health.

Springfield, Ill., Sept. 30, 1889.

**Sanitary Condition of Los Angeles.**

*To the Editor:*—In response to your editorial entitled "The Sanitary Condition of Los Angeles" (Sept. 28), pardon me for a statement of the facts. "The paragraph by a local paper" is simply claptrap, which grew out of a heated newspaper contest prior to the sewer bond election, as the figures will demonstrate.

Los Angeles, with a population of 80,000 inhabitants in 1888, had a death-rate of 8.50 per 1,000. The death-rate for the current year is 8.89 per 1,000 inhabitants per annum. These figures include '95 deaths from consumption from foreign states" for last year, with even a larger proportion for the present year. These figures also include the deaths of the Los Angeles County Hospital (located in the city), which is no less than an interstate and international

hospital as well. I voted for the bonds, but knowing the figures and the facts, I am constrained to say that the "gem of the Pacific coast" has, indeed, a clean sanitary "escutcheon."

Very respectfully,

J. H. DAVISSON, M.D.,

Member City Board of Health.

Bryson-Bonebrake Block, Los Angeles, Cal.

## BOOK REVIEWS.

TRANSACTIONS OF THE GYNÆCOLOGICAL SOCIETY OF BOSTON. NEW SERIES. Vol. I. Boston: Cupples and Hurd, 1889.

This is a handsome volume of nearly 400 pages, containing 29 excellent papers. A prefatory note states that the society, which was founded in 1869, has published seven volumes of its transactions covering the period between 1869 and 1872. The present volume contains papers read since 1879.

ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE-HOSPITAL SERVICE OF THE UNITED STATES FOR THE FISCAL YEAR 1888; pp. 406.

A great deal of interest to the medical reader will be found in this report, which includes, among other matters, a description of the outbreak and management of the recent epidemic of yellow fever in Florida; observations on the natural history of epidemics of yellow fever by Passed Assistant Surgeon John Guitéras, M. H. S.; a report on the food of seamen coming into the port of Philadelphia, by Surgeon P. H. Bailhache, M. H. S.; a report relative to food issued to seamen on merchant vessels arriving at San Francisco, together with a report of scurvy treated during the seventeen years ending June, 1888, by Surgeon H. W. Sawtelle, M. H. S.; selected reports of special operations by various surgeons of the service; reports of a large number of fatal cases, with necropsies. Much credit is due the Surgeon-General, Dr. J. B. Hamilton, for the excellent manner in which his report is presented.

LECTURE ON BRIGHT'S DISEASE. BY ROBERT SAUNDBY, M.D., Edin.; F.R.S.P., Lon.; Emer. Sen. Pres. Royal Med. Soc.; Physician to the Birmingham (Eng.) Gen. Hosp., etc., etc., etc. With fifty illustrations. New York: E. B. Treat, 771 Broadway; 1889; pp. vi, 290.

In this attractive volume the writer has set forth, in a lucid and readable form, the results of thirteen years' clinical and pathological study of Bright's Disease. The reader cannot fail to be pleased, entertained and instructed by its perusal, for it is one of those books that are "easy to read," while replete with information. It is

thoroughly practical and admirably suited to the needs of the practitioner. The various chemical and microscopical tests for the detection of the disease are well described, and the classical descriptions of the various clinical features of disease are admirably illustrated by short selected reports of the author's cases. The work is divided into three sections, with subdivisions of chapters as follows:

Section 1.—General Pathology:

Chapter I. Albuminuria.

“ II. Pathology of Dropsy.

“ III. Pathological Relations of Tube Casts.

“ IV. Cardio-Vascular Changes.

“ V. Pathology of Polyuria.

“ VI. Pathology of Uræmia.

“ VII. Retinal Changes.

Section 2.—Clinical Examination of the Urine:

Chapter IX. History-Classification-Etiology.

“ X. General Anatomy of the Kidney.

“ XI. Febrile Nephritis.

“ XII. Lithæmic Nephritis.

“ XIII. Obstructive Nephritis.

“ XIV. Complications.

“ XV. Treatment of Lithæmic Nephritis.

Books of this description do not gather very much dust on the shelves of the general practitioner.

## MISCELLANY.

HEALTH IN MICHIGAN.—For the month of September, 1889, compared with the preceding month, the reports indicate that typho-malarial fever, whooping-cough, typhoid fever (enteric) and diphtheria increased, and that cholera morbus, erysipelas and inflammation of bowels decreased in prevalence.

Compared with the preceding month, the temperature in the month of September, 1889, was lower, the absolute and relative humidity were about the same, the day ozone was less, and the night ozone was slightly more.

Compared with the average for the month of September in the three years, 1886-88, cholera infantum, inflammation of kidney, whooping-cough and cerebro-spinal meningitis were more prevalent, and influenza, diphtheria, puerperal fever and scarlet fever were less prevalent in September, 1889.

For the month of September 1889, compared with the average of corresponding month in the three years 1886-88, the temperature was slightly lower, the absolute and relative humidity were about the same, the day ozone was less, and the night ozone was more.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of September, 1889, at 34 places, scarlet fever at 20 places, typhoid fever at 47 places, and measles at 7 places.

Reports from all sources show diphtheria reported in 13 places more, scarlet fever at 2 places more, typhoid fever at 7 places more, in the month of September, 1889, than in the preceding month.

The bulletin "Health in Michigan," heretofore issued by the Secretary of the State Board of Health have mentioned the increase and decrease of those diseases in

which a difference of seven or more was shown between the per cents of reports, stating the presence of the disease in the current week or month and in the preceding week or month, or in the corresponding month in previous years.

Hereafter those diseases will be mentioned of which the comparison shows an increase or decrease of 25 per cent from the preceding week or month, or from the normal as the case may be.

The new method has the effect of calling attention to changes in the prevalence of diseases, which like diphtheria and scarlet fever are important, yet which are not usually reported by a very large number of observers, and, therefore, under the old plan would not be mentioned.

### CONCEALED PREGNANCY—ITS RELATIONS TO ABDOMINAL SURGERY.

*Read in the Section of Obstetrics and Diseases of Women, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY ALBERT VANDERVEER, M.D.,

PROFESSOR OF DIDACTIC, ABDOMINAL AND CLINICAL SURGERY IN THE ALBANY MEDICAL COLLEGE.

A half century ago a distinguished German surgeon was called in consultation by a very competent obstetrician to a case in which the patient had apparently been in labor for three weeks. A Cæsarean section was decided upon, and the abdomen opened, when, to the discomfiture of all, nothing but intestines distended with gas were found. That the Professor was chagrined and in a vindictive frame of mind, was demonstrated by the after-treatment, for he kept the abdomen packed in ice, applied two hundred leeches to the abdominal walls, and in addition subjected the woman to three bleedings. The patient recovered, and doubtless ever after desisted from trifling with the resources of surgery. This case has never been reported as a successful Cæsarean section. From then until now errors relative to the diagnosis of pregnancy, as a complication of abdominal section, have occurred, and doubtless will continue to occur; no one has been free from the liability to this error. The most eminent and painstaking surgeon of extensive observation, as well as the operator of few opportunities, have all the same experience.

When mine came I must confess to you that I felt not a little humiliated. I asked myself after a careful review of my notes, and those of my assistant, "Have I exercised all the care that is possible in the examination of my case, and has my diagnosis been based upon good judgment?" Text-books on obstetrics and gynecology furnished but little aid or comfort. The few cases reported were widely scattered, and many found in the tables accompanying this paper were se-

cured only after diligent, personal inquiry. Many of the mooted questions of abdominal surgery have already been settled, and we are little benefited by papers devoted to the treatment of the pedicle, drainage, or the detailed histories of cases. I have thought that I might be able to contribute something for the benefit of the profession, by giving the results of my investigation of this subject. I shall relate to you the histories of two personal cases of exploratory incision in which pregnancy as a complication of fibroid tumor occurred, and which was not diagnosticated prior to the operation, either by myself or my colleagues, after repeated careful examinations. I purpose treating the subject with perfect frankness. I have collected all reported cases, wherein the same conditions existed, and personal inquiry has secured the histories of many others which are now presented for the first time. That the table is incomplete I know, for some of the operators have either perverted the histories of their cases, or have suppressed them altogether. This latter statement is capable of abundant proof. We shall later, when we come to the consideration of the table of cases, collect such facts as seem warranted from the clinical histories, and endeavor to draw from them such conclusions as are justifiable.

*Case 1.*—Abdominal Section, Exploratory. Operator A. VanderVeer, M.D. Operation October 7, 1887.

Mrs. E. C. W., æt. 34, native of United States, married and by occupation a housewife. Family history decidedly tubercular. Patient gave history of past ill-health, but aside from an expression indicative of much pain and suffering, she seemed physically strong. First menstruation at 13, scanty and painful; menstruation always irregular; has suffered for extended periods from amenorrhœa. No children, no miscarriages. Was treated during 1883 for ulceration of the cervix with leucorrhœa. June 5, 1887, was the date of the return of her menstruation, but no flow appeared, and on June 25, 1887, she noticed a tumor in the left iliac region which grew rapidly and became very painful. Patient had a slight show July 4, also noticed a slight tingling and swelling in the breasts; no nausea or vomiting. September 30 I gave her a careful examination at my

NOTE.—For much that pertains to the preparation of this paper, collection of cases, etc., I am indebted to Dr. Willis Goss Macdonald, Assistant in Abdominal Surgery, Albany Medical College; and I wish also to extend my thanks to those gentlemen who were so kind as to send me the history of their own cases hitherto unpublished, and other references.

office and made the following notes: Breasts slightly enlarged and tender, areola not markedly pigmented; abdomen, to the height of the umbilicus, irregularly distended. Palpation revealed a hard tumor on the left side, and a softer one (semi-fluctuant), on the right side. No absolute signs of pregnancy after repeated examinations. Per vaginam, a natural cervix could be felt high up and a mass at the left of the uterus was distinctly made out. I was in much doubt as to her condition, taking into full consideration the probability of a normal or extra-uterine gestation, also of fibroid or fibrocystic tumor of the uterus. I advised that she enter the Albany Hospital for further observation, which she did a few days later. Upon examination and consultation with Drs. Boyd and Townsend, having agreed upon the physical signs already detailed, and having introduced the sound into the uterus three inches without result, in view of the distress and great pain of the patient an exploration was deemed advisable. A full explanation was made to the family, an operation advised and consented to by them, having in view the great probability of an ectopic gestation. Abdominal incision revealed two fibroids upon the left of the uterus, subperitoneal in character, and the remainder of the uterine tissue, especially upon the right side, seemed involved by multiple myxomata of a softer consistency. Adhesions were very general, precluding its removal. No further operation being advisable, abdomen was closed. Patient went on well until fifth day, when localized peritonitis developed and rapidly became general. On evening of sixth day abdominal wound opened in consequence of great distension of the bowels, due in part to peritonitis and obstructive pressure of fibroids. A large dressing was saturated with serous effusion. Wound was brought together by strapping. Next morning drainage was introduced, peritonitis subsided in a day or two, and the case went on to recovery. Discharged from hospital November 8, 1887, abdominal wound completely healed. November 13 I visited her at a friend's home and found her presenting a very good condition of health, and able to move about the house. Advised the use of electricity, and requested her to let me know later on how she progressed.

December 24, Dr. H. F. C. Miller, of Rensselaerville, N. Y., who had originally referred the patient to me, visited me and stated that he had been called to attend Mrs. W. a few days previous. Arriving at her house he found her partially delivered of a six months' fetus. The doctor delivered the placenta, noticing quite an enlargement of the abdomen remaining. Patient recovered from her abortion slowly, and since I have had no opportunity for an examination.

*Case 2.*—Abdominal Section, Exploratory. Operator A. VanderVeer, M.D. Operation May 11, 1888.

Mrs. M. M. S., æt. 35, native of United States, and by occupation a housewife. Family history excellent, and before puberty enjoyed good health. First menstruation at 14, always regular, but suffered from dysmenorrhœa and menorrhagia. The menstrual blood was always clotted. Married seven years, no children, no abortions. Three years previous had an attack of general peritonitis, from which she made a good recovery. Four years ago began to have a dull, dragging pain in the right iliac region, and extending down the thigh. A very competent gynecologist was consulted, who regarded the trouble due to the pressure of a displaced uterus.

For the last eight weeks she had menstruated but one day, at the time for her menstruation. About the middle of March, 1888, patient noticed a small hard tumor in left iliac region which gave rise to little discomfort. The tumor grew very rapidly after discovery and was very painful, requiring the free use of anodynes to keep the patient comfortable. The breasts were tender, but the areola not markedly pigmented. The tenderness of breasts always occurred with menstruation. I saw her at her house in consultation with Dr. J. R. Davidson, her family physician, May 6, 1888. Upon palpation I found a growth in the left iliac, hypogastric, and extending upward in the umbilical regions and rather beyond the median line. It was very tender, nodular and boggy to the touch. Upon percussion was perfectly flat and did not fluctuate. Auscultation revealed no sign. Per vaginam the cervix could be made out far back towards the sacrum, but the body of the uterus could not be outlined. In the cul-de-sac of Douglas a body the size of an egg could be defined. Bimanually cervix and growth moved as a single body. The uterine sound passed  $3\frac{1}{2}$  inches. Ballotement failed to elicit anything. The vagina was not distinctly tinged. The patient was examined by Drs. Boyd, Townsend and myself a few days later. Although in consultation the intra-abdominal condition could not be agreed upon, from the urgency of the symptoms an exploration was deemed advisable, believing the growth to be a multiple, uterine fibroma, with a view to hysterectomy or the removal of the uterine appendages. The abdomen was opened by the usual median incision, and upon examination of the growth it seemed sarcomatous in its nature, springing from the broad ligament and the body of the uterus. From the extent of the pelvic adhesions, the great vascularity of the growth and the bad prognosis of sarcoma, its removal was not undertaken. The fourth day after the operation localized peritonitis occurred, but yielded kindly to salines and ice coil locally. In the morning of the tenth day a slight show was noticed, and at noon the patient aborted, the fetus being about four months. There was no flooding. Her condition rapidly became more

serious, and she died from exhaustion May 24, 1888. Autopsy three hours after death. Uterus implicated by large fibromyxoma, partially subserous in character, was studded with hard, nodular excrescences, thirteen in number, and which

In addition to my personal cases I shall take the liberty of presenting to you abstracts of the histories of cases which illustrate the conditions that are properly open for discussion.

N-1.

completely surrounded the uterus. The great mass of the uterine tumor lay to the left of the uterus. There were extensive adhesions of tumor to the intestines and bladder. Cavity of uterus 4 inches in depth, and contained small portions of

the placenta. There was no fluid in abdominal cavity, and but slight evidence of recent peritonitis. No further examination was made. For a clearer idea of the tumor I invite your attention to the photographs here presented.

*Case 3.*<sup>1</sup>—Abdominal Section, Exploratory. Operator Dr. Cornelius Kollock. Operation May 21, 1889. *Abstract.*—A. C. F., *et.* 28, colored, married and has one child, now 10 years old. General health apparently good. Four years ago she first noticed a fullness of the abdomen, more to the right than the left side. When I first saw her, (May 10) she was very much distended. The prominence was central and very high up. Tumor movable, hard and nodular. Fluctuation could not be elicited. Menstruation normal in every particular. She positively affirmed that she never missed a period save when pregnant the first time. There was no vaginal tilting, the os uteri was closed, and the cervix as hard as cartilage. The sound was introduced nearly 4 inches into the uterus, and she did not present a single symptom of pregnancy. The tumor had become so large that it produced severe dragging, dyspnea and discomfort. An exploratory incision disclosed a very large subperitoneal fibroid springing from the fundus by a broad pedicle. The uterus was occupied by twenty-two other fibroids varying in size from an orange to a cherry. A supravaginal hysterectomy was done, and the uterine cavity found to contain a macerated fetus of two and one-half or three months. The patient was doing well June 1. A recovery.

*Case 4.*—Abdominal Section for Multiple Fibromyxoma. Operator M. Péan. Operation Decem-

<sup>1</sup>The abstract of this case is made up from notes kindly furnished by Dr. Kollock, who has frankly stated the facts in this and another case, and generously offered them for publication.

ber 15, 1874. *Abstract*.—Madame B., æt. 37, a widow for several years, always sterile. For several years had suffered from severe menorrhagia. Recently tumor had grown very rapidly and flooding had been very exhausting. M. Péan diagnosed fibromyxomata, and proceeded to their removal, which he did by enucleation. The operation was followed by abortion on the second day. Gestation had advanced between four and five months. Patient recovered.

*Case 5*.—Abdominal Section for Fibromyxoma. Operator Professor Freund, Strassburg, contributed by Dr. J. W. Poucher, Poughkeepsie, N. Y. *Abstract*.—Patient æt. 50, married many years, always sterile. Fibroid had existed for some time longer than discovered pregnancy. When the uterus was opened, to his own and everybody's surprise, Freund brought out a buxom fetus which also seemed very much surprised, for it immediately began to cry. It proved to be at least eight months old and all right. There was also a large fibroid which was very vascular. A supravaginal hysterectomy was done to complete the operation, and the result is unknown to me. This case is now reported for the first time.

*Case 6*.—Abdominal Section, Exploratory; operator, Robert Barnes, M.D.; operation January 7, 1877. *Abstract*.—Mrs. C. had been married for several years; no children or abortions. Always menstruated punctually until three months ago, without excess, since which time menstruation has been suspended and pelvic pain has arisen, with dysuria, retention and intra-pelvic pain, accompanied by vomiting. A fortnight ago swelling in the hypogastrium from pelvis upward became marked, and the abdomen was found partly filled by a tumor taken to be a fibroid. January 24, 1877, Dr. Barnes saw the case and found an enlargement of abdomen extending to a little above umbilicus on the right side and not quite so high on the left. It was tender and lumpy, and the os uteri was felt high above the upper edge of the symphysis pubis, small and compressed transversely. Sound passed two and one-half inches. Behind tract of sound, and apparently behind tract of uterus, another dense tumor could be felt. By rectum the mass could be felt rounded, filling sacral hollow. Two days later Drs. Baber, Braxton-Hicks and Barnes met in consultation and discussed the probabilities of the case. Under ether an attempt was made to dislodge the tumor from the pelvis, which was only partially successful. They thought the probability preponderated in favor of an ovarian tumor partially solid. It seemed impossible that fibroids could be developed so rapidly. The condition of pain, retention, vomiting and commencement of strangulation of impacted mass made it imperative to give quick relief. Gastrotomy was decided upon with this end in view. Abdominal section revealed general peri-

tonitis. On summit and side of tumor were numerous nodular projections. Trocar plunged in and a little blood and foul air was obtained. Tumor and uterus were removed by supra-vaginal amputation. Uterine cavity contained three months' fetus. Death from shock.

*Case 7*.—Abdominal Section for Fibro-Myxoma; operator, Dr. Alex. Patterson; operation, December 11, 1884. *Abstract*.—Mrs. M., aged 36, married nine years, menstruation always regular until last few months; now it was entirely suppressed. For years menstruation has been profuse. August, 1884, the patient accidentally discovered tumor in left side of abdomen about the size of a small plum. In September tumor began to increase rapidly and to be accompanied by great pain. September 22d a specially qualified consultant was called, and his diagnosis was hæmatocele in Douglas' pouch and his advice against operative procedures. Matters becoming more serious an eminent surgeon was called, who gave his opinion in very decided terms that the tumor was uterine fibroid and should be left alone, as an operative procedure would only hasten a fatal result. I was called December 21st and thought the case to be one of fibroid that could be removed and the patient recover. In the left iliac fossa, close to the pelvic brim, the tumor was most readily encountered. It was traceable across the lower abdomen, getting lower to the brim on the right side. The growth was firm, elastic, nodular, and painless on pressure. Per vaginam, pelvis filled by small mass, and the vagina was roofed across. Uterus completely fixed. Wishing to be sustained I called a medical friend well versed in such matters, and after a prolonged examination he decided the case to be one of ovarian disease, probably double, and that it should be removed. An endeavor was made to introduce the uterine sound, but it could only be made to pass one and one-half inches. Abdominal section revealed multiple fibro-myxoma. A supra-vaginal hysterectomy was done and uterine cavity found to contain a four months' fetus. Patient recovered without a bad symptom.

*Case 8*.—Abdominal Section, Multiple Fibroid; operator, Dr. George Granville Bantock; operation April, 1884. *Abstract*.—When patient first came under his notice, two years prior to operation, the tumor was of small size, but menstruation was excessive. Whether as a result of medical treatment or otherwise, it was a singular fact that the menorrhagia diminished until the flow became quite moderate and even scanty, while the tumor kept on growing. For over three months before operation menstruation had been absent. As the patient was single his suspicions were not aroused, and it was impossible to examine the uterine body, for the cervix was so drawn up that the os could only be touched with the tip of the finger, while the uterus was covered in

front by one of the tumors. After separating omental adhesions to the larger of the two tumors, which had undergone cystiform degeneration, and turning out the whole mass, it was easy to secure a very good pedicle at the level of the internal os. He confessed he was rather glad he had not diagnosed the pregnancy, for had he done so he probably would not have performed the operation. Uterus contained three months' fetus. He was happy to say that when last seen the patient was in excellent health and even contemplating marriage.

*Case 9.*—Abdominal Section, Supra-Vaginal Amputation of Pregnant Uterus, Complicating a Multilocular Fibroid Tumor; operator, Dr. James H. Etheridge. *Abstract.*—Mrs. A. B., aged 34, no children, first experienced uterine symptoms four years ago. Two years later suffered from retroversion and impaction of the uterus, at which time a sub peritoneal myoma was diagnosed. In May, 1886, four years since first symptoms, patient suffered from distressing nausea. Mammary changes supervened. In the ensuing three months the tumor grew rapidly, and Dr. Knox diagnosticated pregnancy. At the expiration of three months he decided to produce abortion. August 1, 1886, sound was introduced into uterus four inches. Its withdrawal was followed by a small amount of blood, the nausea and vomiting ceased, and the mammary symptoms disappeared. Nothing further followed indicating the previous existence of pregnancy or abortion, and the conclusion was reached that conception had not occurred. The rapid encroachment on the abdominal organs, her diminishing strength, emaciation and suffering were progressively killing her. From external examination it was found that the tumor extended from the right iliac fossa across the abdominal cavity in a straight line to the spleen. Its length was apparently double or treble its width. It was freely movable, free from adhesions, and solid. It presented great tenderness in right iliac fossa. Per vaginam, the cervix uteri was found very high up in the left iliac fossa, and the fundus uteri was apparently thrust into the right iliac region. The whole tumor moved with the uterus. A very slight resiliency, offered to conjoined manipulation, led me to think that I had to do with a fibro-cystic tumor of the uterus. The sound entered the uterus four inches and seemed to pass toward the umbilicus; tumor was removed by supra-vaginal hysterectomy. Patient died from septicaemia. Examination of the tumor showed it to be fibro-myxomatous, and that the uterine cavity contained a three months' fetus lying in its unruptured membranes. Fetus was evidently alive at time of operation. The cervical canal was five and one-half inches long. Weight of tumor, 10 pounds.

*Case 10.*—Fibro-Myxoma of Uterus Compli-

cated by Pregnancy. Reported by J. Lucas Worship, Esq. *Abstract.*—Mrs. C. C., aged 35, married two and one-half years, family history good, previous health good. Six months after marriage she suffered from severe pain in the left iliac region, but continued her service. Later she began to enlarge and was examined repeatedly, but no signs of pregnancy ever elicited save amenorrhoea. Never suffered from menstrual disorders. Tumor grew very rapidly and was irregular. Cervix was very high, firm and near the sacrum. A diagnosis of malignant tumor of the uterus was made and palliative treatment instituted, but the patient died in two months. Post mortem examination revealed multiple fibro-myxoma of the uterus and pregnancy. Period of gestation at death, six months.

*Case 11.*—An abstract of a personal letter from Prof. Czerny, of Strassburg. The case was operated upon January 7, 1881, for supposed ovarian cyst: The cervix uteri was elongated, but not well defined from the fundus. No foetal pulsation. The uterine sound passed, without any obstruction whatever, 21 centimetres, and, as I thought at the time, through the tube into the abdominal cavity. On making the incision through the abdominal walls I at once recognized a gravid uterus and immediately closed the wound. I had evidently cut down to a gravid uterus, which was in an anti-flexed position and contained a large quantity of liquor amnii. I must add that the patient, aged 31 years, who in her capacity as midwife had delivered seventy-five women, strenuously denied that she was pregnant, and as firmly asserted that she had had the menstrual flow within a few days. There was some deposit of pigment about the nipples and areola. Without any bad results following the laparotomy she was safely delivered April 28, 1881. Some time after the cicatrix became indurated. This was remedied by making elliptical incisions and applying sutures, with good result.

#### INDICATIONS FOR OPERATION.

A study of the clinical histories, especially in the cases of fibro-myxoma, shows that there was an immediate demand for operative procedure. Robert Barnes so tersely states the indications for abdominal section in his case (see case 6) that the repetition is useful: "The condition of pain, retention, vomiting and commencing strangulation of impacted mass made it imperative to give quick relief." To these symptoms exploratory laparotomy reveals that other often fatal condition, peritonitis. Alex. Patterson's case was equally unpromising but happier in its results. Pain has been a prominent symptom in nearly all of the cases, often requiring the continuous use of anodynes. Palpation gave so much distress that, if done at all, it was imperfect and unsatisfactory. The rapid growth of the tumor has led

to dyspnea, dysuria and constipation, or to more active obstruction of the bowels, œdema of the extremities, vomiting, emaciation and peritonitis. Universal experience has shown that temporizing with cases wherein there are symptoms such as have been related has been uniformly disastrous. The case of J. Lucas Worship, Esq., has been introduced in this article for the purpose of illustrating this point. Teachers have been often too prone to advise the waiting for extended observation. It seems to me that Mr. Lawson Tait has carefully and clearly enunciated that which is the best practice in one of his numerous controversial papers (*Am. Jour. Obstetrics*, vol. xxi, p. 295), in which he says: "Conditions within the abdomen are such that the life of the patient is evidently threatened, or the conditions combine in such a direction as to defy ordinary treatment and make life unendurable. Do not let any doubt as to accuracy of diagnosis stand in the way of an exploratory incision, for this will at once make a complete diagnosis possible and open a road for successful treatment."

#### DIAGNOSIS.

The influence of gestation upon fibro-myxoma demands our consideration. The consistency of the abdominal tumor has been variously described as firm, doughy, soft, fluctuant, and, indeed, the sense of fluctuation has led the surgeon more than once to puncture the tumor with the needle of the aspirator, or trocar. There can be no reasonable doubt that the different degrees of density are dependent upon three conditions, viz: the structure of the tumor, its situation, and certain degenerative changes. The growths made up largely of muscular elements are more readily affected by the increased intra-pelvic circulation of pregnancy, become more cedematous and grow more rapidly, than those in which fibrous elements preponderate. Intra mural fibro-myxomata, from their more intimate connection with the uterine walls, exhibit more active metamorphoses than do sub peritoneal ones with slender pedicles. Pregnancy may also bring about necrotic degeneration and softening from pressure. If the foregoing facts are sufficiently established, then sudden enlargement and softening of pre-existing fibro-myxoma is a valuable sign of pregnancy. But this rapid increase in volume has not been uniformly observed (*Gusserow Cyl., O. G.*, vol. ix, p. 300). Again, as this rapid growth is more frequently dependent upon increased vascularity, causes other than pregnancy may operate similarly. Tumors largely myxomatous often markedly enlarge during menstruation and grow with great rapidity. On the other hand, fibro-myxoma, in which sarcomatous degeneration takes place, or primary sarcoma of the giant, or small round cells type, are very rapid in their development and are attended with great pain.

In the case of Worship (l. c.) the diagnosis of malignant disease of the uterus was made. *A priori*, sudden increase and softening in a fibro-myxoma, to be of value as a presumptive sign of pregnancy, is dependent upon the exclusion of primary sarcoma, or sarcomatous degeneration, and the soft and rapid growing variety of fibro-myxoma.

For these reasons, in those cases where the diagnosis of pregnancy has been made upon the observance of rapid increase in size and softening in the fibro-myxoma, it is to my mind, although quite enough to arouse suspicion, based upon insufficient evidence. However, in connection with amenorrhœa and mammary changes it is of great value, and yet has not been referred to with uniformity by writers. Ectopic gestation may occur in these cases, giving rise to the same changes in the tumor (see cases of Smutz and Bayle). Amenorrhœa is a valuable symptom when it occurs. It will be noted that it occurred in eleven of the twenty-six cases, the study of which form the basis of the greater portion of this paper; yet there are circumstances which may materially modify its value as a symptom. For example, in my first case the patient gave a history of having suffered for extended periods from amenorrhœa. Again, in the case reported by Bantock the menstrual flow had been growing more scanty for a long period and finally ceased. The menstruation may continue, or an irregular flow may exist during pregnancy (Mundé, Bayle, Gusserow, and others). Abortion in cases of fibro-myxoma is most frequently induced by flooding. The sympathetic mammary disturbances which are observed in pregnancy were noted in four of the cases, but they are of themselves of no great value. In my second case they were present, but not more prominent than at any menstrual period. "The gastric, mammary and nervous symptoms of pregnancy sometimes result from ovarian disease." (Thomas.) Abdominal palpation, especially in the earlier months, can add but little in the elucidation of the problem and often has misled surgeons of great ability. Auscultation may reveal a bruit, but who will say that it is the bruit of fibroid or of pregnancy? Later both palpation and auscultation are invaluable, revealing ballottement, quickening, and the fetal heart sounds. The sign of pregnancy, to which, in later years, Braxton-Hicks has called particular attention, the alternating contraction and relaxation of the pregnant uterus, may be entirely obscured by the fibro-myxoma. English operators have laid great stress upon this sign.

Per vaginam, the vaginal venous injection observed in pregnancy does not differ materially from that occurring with the large fibro-myxoma, in which a concealed pregnancy may occur. In none of the cases here reported were there such changes in the cervix uteri as are regarded char-

acteristic of pregnancy. The cervix has been de-  
scribed as firm, compressed transversely, elongat-  
ed, and has been located high up behind the  
symphysis pubis, or back in the hollow of the  
sacrum, or operators have been unable to palpate  
it at all. Because of these distortions Hegar's  
sign of early pregnancy has been of no assistance.  
The use of the uterine sound in both of my cases  
and in nearly all of the cases detailed (in table 1)  
has not aided in the diagnosis. So complete has  
been its failure that any facts determined by it  
should not enter into one's judgment of the case,

and I am in great doubt if it should be used at all. Besides, the great difficulty of introduction and the danger of perforating the uterine walls are not altogether innocuous. In sixteen cases there were either no signs stated, or an emphatic statement that there were no signs of pregnancy present. Granted that in a given case of fibro-myxoma the diagnosis of pregnancy is made, how does the operator know that the gestation is not ectopic, or that it is not located in a rudimentary

mentary horn of a bicornate uterus. Experience has shown that these errors have occurred, and if the diagnosis is to be exact, differentiation is demanded. But the possibility of the diagnosis of simple ectopic gestation before rupture of the tubal sac and hæmorrhage is at least vigorously assailed, not only abroad, but in America. Manifestly this is no time for entering into the discussion of the merits of this last important question. I would not have it understood that, in my opinion, the diagnosis of early pregnancy as a complication of fibro-myxoma, *i. e.* before the fourth month, is impossible in all cases, but that the diagnosis is at the best a matter of presumption, and that it is often impossible when immediate operative interference is demanded. With no desire to be critical, I must say that many of our text-books give very meagre accounts of pregnancy as occurring with fibroids. Barnes, after writing at length, came to the conclusion "that the chief characteristic in the complication was the want of uniformity in the uterus." His statement regarding the diagnosis of pregnancy with ovarian cyst is equally as clear. Thomas makes no mention of the complication, and Byford, after referring to the mistakes made by himself, Sims, Wells and others, says: "A careful examination of the cervix uteri, the abdomen and the breasts for evidences of pregnancy will seldom fail to make the diagnosis of this complication clear." Hart and Barbour, Emmett, Hewitt, Simpson, Scanzoni, Courty and many obstetric authors either do not mention the complication, or advise waiting. Prof. Skene relates the histories of two cases wherein pregnancy occurred with fibroids, and in which the diagnosis was not made until months later. Karl Schroeder expresses the

opinion "that it may be exceedingly difficult to differentiate between simple fibroids and fibroids complicated by pregnancy." Hirst (*Am. Sys. Obstetrics*) says: "In rapid growing soft myxoma the diagnosis may be exceedingly difficult or impossible." Gusserow (*Cycl. O. G.*, vol. ix) rather neglects early pregnancy, but attributes the error in the latter stages to carelessness. The editor of the last edition of "Speigelberg's Midwifery," 1887, makes the statement that, "as a rule, there is very great difficulty, especially in the cases of intra-mural growth, since, at any rate during the first four or five months, they often conceal the pregnancy. The most careful examination may not elucidate the case." After the fourth or fifth month the error has occurred but three times. In Karström's case ascites as a complication obscured the diagnosis. In the case of Prof. Freund, of Strassburg, the patient, 50 years old, always sterile, presented no symptoms that led even to a suspicion of pregnancy. It is only fair to Dr. Bernays to say that he suspected the possibility of pregnancy, but from the history of the case there seemed no ground for the suspicion, and the suspicion was not confirmed in consultation.

There is no error in diagnosis which brings the physician into so much undeserved disrepute in the popular mind as a failure to recognize the presence or absence of pregnancy. Yet I am familiar with several cases where this error has either led to abdominal section, or all the preparations for one have been made. Recently a member of the British Gynæcological Society amused a meeting exceedingly by relating a case wherein a specially qualified operator journeyed many miles to a case.

After his arrival, late in the afternoon, he examined the case carefully, decided the growth to be fibroid, and that it should be removed. Being much fatigued by his journey he decided to remain and perform the operation the following morning. Early the next morning he was gravely informed that his services would not be required, as the patient had, during the night, given birth to a fine baby, and the tumor had disappeared. Nor does this experience stand alone. Others have brought cases to the operating table with a dilating os uteri. Of the nine cases of simple pregnancy found in the table, five of them occurred early in the history of abdominal surgery, when methods of differential diagnosis were not as well taught and practiced as now. I want to call your attention particularly to the case of Dr. Wm. Varian. From the history of the case I have no doubt that many, if not all of us, would have been led into the same disagreeable error. Dr. Prince had a similar experience. The frequency of the complication of undiagnosed pregnancy in single women will be noted in the tables. I am reminded of a remark attributed to the late Prof. MacNaughton, in answer to the inquiries of an anxious mother who had called him very late one night to see her daughter, who had just returned from a ball in a blissful state of intoxication: "Ah, madam, the best slip, the most cautious fall; your daughter will be better in the morning." It is well to have the quaint saying of the good old Scotchman always in mind when single women present themselves with abdominal tumors, and we should never be in a hurry to operate. The history obtained from the patient, and often from her relatives as well, will be full of deceit at least, and may be, as in Prince's case, made to fit minutely a variety of actual disease. Such cases should be subjected to the most painstaking physical examination; nor should any protestations upon the part of the patient deter the surgeon from making a complete examination of the vagina and breasts, as well as of the abdomen. His judgment must be based entirely upon the physical examination.

Pregnancy as a complication of ovarian cyst is met with considerable frequency, and is not always diagnosed before operation. We can hardly enter into the discussion of the symptoms, for in the twenty-eight cases that go to make up the table none are stated save in one case, amenorrhoea. In some of the cases the operators state that there were absolutely no signs of pregnancy. The period of gestation in twenty-one cases was before the fourth month. Three others occurred in single women, and the remaining two cases were at about the fifth month. The presumptive signs of pregnancy occurring with fibro-myxoma are, in cases of ovarian cyst, obscured or modified; yet to some of them greater diagnostic value can be attached. Close attention to men-

strual disorders will occasionally determine the fact that the patient's menstruation has been perfectly normal until a recent period, when it has ceased altogether. This is sufficient ground for suspicion. The examination of the breasts should be a matter of routine; yet the evidence obtained will be of no great value. The vaginal examination here will be of greater value than with fibro-myxoma. If the uterus can be palpated and found regularly enlarged, yet independent of the tumor, if the cervix is softened and os patulous, if the vaginal walls are tinted, then there exists strong presumptive signs of pregnancy. Hegar's sign in such cases, if demonstrable, makes the diagnosis absolute. Palpation of the abdomen in the earlier months, when the error occurs, is of no value. When the uterus rises into the abdomen, then palpation and auscultation are with ballottement, and the sign of Braxton-Hicks sufficient, as a rule, to make the diagnosis. But the pregnant uterus may be obscured anteriorly by the large cyst; it may be retroverted and impacted in the pelvis, or drawn up and dislocated laterally by the rapidly increasing cyst, so that it will be impossible to explore it satisfactorily; then the diagnosis is impossible. When the slightest suspicion of pregnancy exists in connection with ovarian cyst, the use of the sound is absolutely unjustifiable, although it seems, in the cases where it was used, that it only confirmed the error in diagnosis. Accumulated experience has shown conclusively that abdominal section for ovarian cyst in the pregnant woman should be done generally and without the previous induction of abortion.

*Conclusions.*—1. Finally, from the study of the seventy cases, I am convinced that the errors of diagnosis are dependent, in a large proportion of the cases, upon conditions which make it absolutely impossible, when these conditions recur in other cases, to avoid the same diagnostic conclusions.

2. That it is the duty of every operator, before making an abdominal incision, to secure personally, or by a specially qualified assistant, a fully classified, written statement of the facts which go to make up the clinical history of the case, together with the results of the physical exploration made by the operator and his consultants, using a formal blank statement (that of Sir Spencer Wells, for example), so that no facts may be omitted. That no part of this duty should be delegated, except under supervision, to internes of hospitals.

3. That the probable diagnosis should be based upon the physical signs contained in the notes, corroborated, with few exceptions (unmarried and ignorant patients), by the rational signs contained in the clinical history, and not by simple abdominal palpation and "the dim light of a pelvic examination."

4. That whenever the slightest probability of pregnancy exists, it should be fully explained to the patient and her friends.

5. That the necessity for operative relief and the consequences of delay or neglect should be carefully stated to the parties interested, before obtaining their formal consent to the operation.

6. That it is the duty of every operator to report fully all such cases, that the methods of diagnosis may be improved, if possible.

7. That it is the duty of the profession at large to maintain that pregnancy may be absolutely concealed, especially prior to the fourth or fifth month, by other intra-abdominal conditions.

## CHRONIC ENDOCARDITIS.

*Read in the Section of Practice of Medicine at the Fortieth Annual Meeting of the American Medical Association, June 28, 1889*

BY FRANCIS DELAFIELD, M.D.,  
OF NEW YORK.

It is proper that I should offer to you some reasons for selecting so ordinary a disease as is chronic endocarditis as the subject for this paper. But the ordinary diseases are, after all the important ones, and often as we see them we never really know them well enough. Any fresh record of facts, any new way of grouping, or of looking at these facts must be of some little service. It is the object of this paper, therefore, not to give a systematic account of endocarditis, but to draw attention to some features of the disease; not to give a history of the views of other observers, but to state simply what I have put together from my case books and post-mortem records.

Of the ordinary diseases few are more common than is chronic endocarditis. In few of them is there so great a variety in the severity of the symptoms. From the condition of a trifling inconvenience to that of a distressing and fatal disease there seems to be no limit to its various phases. We constantly meet with patients whose heart valves are seriously damaged and who yet enjoy good health, can follow laborious occupa-

tions and are often ignorant that they have any disease. On the other hand, we, with equal frequency see patients in whom the same valvular lesions are attended with the most serious symptoms and with death. It is, therefore, a matter of practical importance to determine as accurately as we can why it is that some of these patients do so well and others so badly. For it is in this way that we are most likely also to determine a rational treatment for the disease.

It seems evident that nearly all the most important symptoms of chronic endocarditis are due to the disturbances produced in the distribution of the blood throughout the body. It is by these disturbances of the circulation that the cerebral and pulmonary symptoms, the loss of nutrition and the dropsy are produced. The problem before us, therefore, is to determine why in some cases of chronic endocarditis there are disturbances of the circulation, and why in other cases there are not.

It might seem at first that the solution of this problem is an easy one, that the disturbances in the circulation are simply in proportion to the stenosis or insufficiency of the valves. A very moderate experience, however, is sufficient to show that this is not the case. The problem is a complicated one, and the disturbances of the circulation are due to a number of causes which act singly or together.

We may enumerate these causes as follows :

The endocarditis.

The dilatation and hypertrophy of the ventricles.

The inflammation or degeneration of the wall of the heart.

The inflammation of the coronary arteries.

The abnormal heart action.

The associated pulmonary emphysema, chronic endarteritis, and chronic Bright's disease.

To follow out the mode of action of all these causes is not possible in a paper of this character. I confine myself to the consideration of three of them : The endocarditis ; the abnormal heart action ; and the secondary and complicating changes in the kidneys. Not that the others are unimportant, but that these three are perhaps the most important of all.

1. The Endocarditis.

In thinking of persons with valvular lesions, we must remember that some of these persons, while under our observation, are suffering from chronic endocarditis, and that some are only suffering from the changes produced in the valve by an endocarditis which no longer exists. In the one case they suffer from a chronic inflammation, in the other from a deformity. It may be indeed that such deformity leads to progressive changes in the cavities and walls of the heart. But this is much less likely to happen than if the changes in the valves are also progressive.

Chronic endocarditis may directly follow acute endocarditis; it may be developed after a long interval in valves damaged by an old attack of endocarditis; it may from the first be a chronic lesion. We find, especially in children, an uninterrupted history of cardiac symptoms beginning with an acute attack and continuing as a chronic disease for years. We find in older persons with marked cardiac symptoms developed late in life a history of an acute endocarditis in childhood, from which they had apparently recovered. We find in adults the gradual development of one cardiac symptom after another, so slow and so gradual that we can hardly date the beginning of the disease.

Chronic endocarditis, when it has once commenced, seems to have a natural tendency to persist and to involve other portions of the endocardium. The cases vary as to the activity of the endocarditis and the intermissions in the course of the inflammation. It is apparently possible for the endocarditis to stop at any time, and the valves will then undergo no further change. Chronic endocarditis is a productive inflammation with the formation of new tissue, but without exudation. In its most active form there is a very considerable growth of cells and also a death of cells, so that the inflamed endocardium is thickened in some places, ulcerated in other, and on the roughened surfaces thus made, thrombi are formed. This is the most active and dangerous form of the disease. In its more chronic form the growth of cells is not as great, the cells do not die, the basement substance is thickened. Although the surface of the endocardium is somewhat roughened, and small vegetations are often formed, there are no thrombi.

In either form of inflammation there may be added degeneration or calcification of the inflamed endocardium and of the thrombi. It may very well happen that the patient, after suffering from the chronic form of endocarditis for years, may then develop the more active form in the same valve, or in one of the other valves.

In the more active form of the disease a large number of the cases run their course within six months from the time of the commencement of their symptoms. A considerable number do not live longer than six or seven weeks. The symptoms are pronounced: Disturbed heart action; delirium, convulsions, paraplegia; cough, hæmoptysis, dyspnoea; nausea and vomiting; dropsy; loss of flesh and strength and anaemia, and a rise of temperature. These patients are apt to get rapidly worse, but there may be intermissions, and the inflammation may stop altogether. It seems evident that in the treatment of these patients we must remember that they are suffering from an inflammation of some activity, and that rest in bed, the use of cold or of counter irritation over the heart are measures likely to be of use.

On the other hand, in the slow form of endocarditis the disease lasts for many years. There are usually intermission in its course, and it may stop altogether at any times. Many of the patients have no symptoms. In those who do, some one symptom is first developed and then, as the disease progresses, others are added. These patients are regularly better for an out of door life, with as much exercise as they are able to take.

## 2.—The Abnormal Heart Action.

It is possible for a chronic endocarditis to run its entire course with a perfectly regular action of the heart. This, however, is the exception. The rule is, that the heart's action is disturbed, and this disturbance is often the most important feature of the disease, and furnishes the principal indication for treatment. Such disturbance of the heart's action may be due to:

a. The endocarditis existing as an inflammation of some activity and producing changes in the heart's action in the same way as does an acute endocarditis.

b. Such a degree of stenosis, or insufficiency of the valves as will mechanically interfere with the heart's action. This often does not become a factor of much importance until the stenosis or insufficiency are well marked, and for this reason it is easy to be deceived as to the character of the lesion.

c. Dilatation and hypertrophy of the ventricles are often present, and certainly have their effect in changing the character of the heart's action.

d. Chronic myocarditis and disease of the coronary arteries produce the most extreme and intractable disturbances of the heart's action. Fortunately they are not very common.

e. Contraction of the smaller arteries throughout the body with increase of arterial tension and venous congestion. This condition, although a frequent complication of endocarditis, nephritis, endarteritis, emphysema, and occurring as an independent condition in some cases of angina pectoris, is yet something concerning which our knowledge is imperfect. Whether contaminated blood irritates the arteries, whether the nervous centers are irritated by the contaminated blood or in what way the contraction of the arteries is produced, we do not know. But such a contraction is produced and lasts for hours, days or months. The same patient may never have but one such attack, or he may have many. In patients who have had many attacks, the muscular coat of the small arteries is thickened. Such a contraction of the arteries at once changes the character of the heart's action. It becomes rapid, forcible, feeble and tumultuous. The degree of the cardiac disturbance is apparently in proportion to the degree and suddenness of the contraction of the arteries, but is not related to the severity or extent of the endocarditis. In the early stages of endocarditis we very often see patients who

complain of dyspnoea on exertion and on lying down with precordial pain. Otherwise they feel perfectly well and have normal urine. We find the heart enlarged, its action rapid and forcible, and a murmur indicating disease of one of the valves. The radial pulse is distinctly tense. If by treatment the arteries are dilated the dyspnoea disappears, the heart's action becomes natural and the patients feel well. Or, in a further advanced and progressing endocarditis we may follow patients for years who, in spite of their endocarditis, feel well except when they have attacks of contraction of the arteries. When they have such an attack dyspnoea and other symptoms are developed and continue for weeks or months. Then as the attack subsides, the symptoms disappear and the patients feel well. The first attacks yield readily to treatment. But as time goes on the attacks are more frequent and more obstinate. The pulse is tense, but small. The heart's action is no longer forcible, but feeble or tumultuous. Occasionally we see patients who go on with a chronic endocarditis for many years, but with few or no symptoms. Then with a slight pleurisy, or pericarditis, or without discoverable cause a sudden, extreme and intractable contraction of the arteries is established, causing the most urgent dyspnoea and continuing up to the time of the patient's death. These attacks of the contraction of the arteries are at first readily relieved by the drugs which dilate the arteries—nitrate of amyl, chloral hydrate, nitro-glycerine, opium and potassium iodide. The patients do well with an out-of-door life and regulated exercise. But as the endocarditis advances and the valves are more damaged, especially by stenosis, these attacks are less readily relieved, and it becomes necessary to keep the patients more and more quiet.

f. Unknown causes which apparently act through the nerves which regulate the action of the heart. These form a large, important and obscure group of cases. In some of these cases the abnormal heart action is associated with advanced disease of the valves, and it is only by the results of treatment that we can discriminate how much of the disturbance of the heart's action is due to the valvular lesion, and how much to nervous influences. The pulse is of low tension, feeble and rapid. The heart's action is feeble or exaggerated. The condition of the patients is often very bad, and yet in some of them very marked improvement is obtained by treatment.

These patients at first require complete rest, then massage and later regulated exercise. The most efficient drugs are digitalis, strophanthus, caffeine, convallaria and barium chloride. The heart seems to be always really a weak heart even though its action is exaggerated. It is often natural to believe that there is degeneration or inflammation of the walls of the ventricles, but

yet after death no such changes are found. In other cases the endocarditis is not advanced, the valves are but slightly narrowed or insufficient, there is little or no change in the size of the heart. The heart's action is rapid, either feeble or exaggerated. The pulse is soft and rapid. The patients often have pain or abnormal sensations referred to the heart, the general health may be very much impaired. Although these patients have endocarditis, yet it is really the abnormal heart action which makes them ill and calls for treatment. Some of these patients are very easily managed, the heart's action soon becomes normal, the pain disappears and the patients feel well, although the lesion of the valve still exists. Some of them, on the contrary, do not improve. The disturbance of the heart's action and other symptoms continue, but yet the patients do not die, nor get worse beyond a certain point. There are, however, occasional cases in which the heart's action becomes very bad, the patients are very feeble and die. After death we find but moderate changes in the valves and no changes in the walls of the heart. The management of these cases is apt to be difficult. Attention to the diet, the general health, the habits, the climate, the exercise is of especial importance. Of drugs, one or other of the cardiac stimulants is often indicated.

3. The secondary and complicating changes in the kidneys.

Of the persons who suffer from chronic endocarditis a large number never have any complicating disease of the kidneys. In the persons who die from endocarditis it is rare to find normal kidneys. In judging of the frequency of the kidney lesions the most certain criterion is the autopsy. During life it is not sufficient to examine for albumen and casts, which are often absent, but the quantity of the urine, its specific gravity, and the proportion of urea to the ounce of urine must also be determined. Advanced changes in the kidneys often exist in patients whose urine is said, after a superficial examination, to be normal.

In persons who die from chronic endocarditis we find :

Chronic congestion of the kidney.

Chronic degeneration of the kidney.

Chronic nephritis.

1. Chronic congestion of the kidney.

The kidneys are of medium size, or large. Their weight is increased, they are hard, uniformly congested, their surfaces are smooth. The epithelium of the cortex tubes is opaque, flattened or swollen. The glomeruli show a dilatation of the capillaries, with more or less thickening of their walls and the swelling of the cells which cover their walls. In the stroma there is nothing but some exaggeration of the subcapsular areas of connective tissue which are found in

normal kidneys. The arteries are normal, the pyramid veins are congested and sometimes dilated. The urine is diminished in quantity at the times when the heart's action is bad, and returns to the normal when it is better. It is apparently never increased except from accidental causes. The specific gravity is usually between 1020 and 1025, but may for a time be down to 1010, or up to 1035. The quantity of urea is rarely less than 10 grains to the ounce, it may be as high as 21 grains. The specific gravity and the quantity of urea must be judged by examining the urine of 24 hours for several days, with the proper allowance for diet and exercise. Albumen and casts are absent or present in very small quantities. The effect of the congestion of the kidneys on their functions is simply to diminish the quantity of urine. The quality of the urine is good, and the exudation from the vessels amounts practically to nothing. Apparently the only way in which this lesion of the kidney can add to the symptoms of the endocarditis, is by the diminution in the quantity of the urine.

## 2. Chronic degeneration of the kidney.

The kidneys are considerably increased in size and weight, weighing together from 16 to 20 ounces. Their surfaces are smooth; the cortical portion is thickened, of pink or white color, the pyramids are red. The gross appearance is that of the so-called large white kidney. The epithelium of the cortex tubes is swollen and opaque. In the glomeruli there is dilation of the capillaries. There are no changes in the stroma, or in the arteries, the pyramid veins may be congested. The quantity of the urine varies with the changes in the action of the heart, sometime abundant, sometimes scanty, sometimes suppressed. The specific gravity is not diminished, nor is the proportion of urea to the ounce decreased. Albumen and casts in small quantities are more frequently present than with chronic congestion. While it is difficult to separate the kidney symptoms from the heart symptoms, yet one has the impression that this kidney lesion is more serious than chronic congestion, and has its effect in increasing the symptoms of the endocarditis, especially the loss of nutrition and the anæmia.

## 3. Chronic nephritis.

A chronic inflammation of the kidneys may follow chronic congestion or chronic degeneration, it is then evidently a direct result of the endocarditis; or it may be developed as an independent inflammation and is to be regarded as an associated and not a secondary lesion.

a. Chronic nephritis following chronic congestion of the kidney. The kidneys remain increased in size, or become somewhat smaller. The capsules are adherent, the surface of the kidney is finally nodular, the consistence of the organ remains hard, and the general venous congestion continues. The epithelium of the cortex tubes

is opaque, swollen or flattened. The tubes may contain coagulated matter. The straight tubes of the cortex and pyramids may contain cast matter. The capillaries of the glomeruli are swollen, their walls are thickened, there is an increase in the size and number of the cells which cover the capillaries. There is a considerable growth of connective tissue in the stroma distributed according to the arrangement of the normal subcapsular wedges. Within these masses of new connective tissue the tubes and glomeruli are atrophied. The walls of the arteries may be thickened, the capillary veins in the cortex may be dilated and their walls thickened. The quantity of the urine varies very much at different times in the same patient, sometimes it is above, sometimes below the normal. The specific gravity falls to 1020 or 1016. The proportion of urea to the ounce is somewhat diminished. Albumen and casts in moderate quantities are regularly present at some time in the course of the disease, but during much of the time they are entirely absent. The patients seems to be especially liable to spasmodic dyspnoea and to loss of flesh and strength.

b. Chronic nephritis following chronic degeneration of the kidney. The kidneys are large, their surfaces are smooth, the cortex thick and white, the pyramids red. The epithelium of the cortex tubes is opaque, flattened or swollen. The convoluted tubes contain coagulated matter, the straight tubes cast matter. The capillaries of the glomeruli are dilated and the cells covering the capillaries are swollen. There are no changes in the arteries. The quantity of the urine varies at different times, often it is very scanty. The specific gravity keeps close to the normal, or may even be above it. The proportion of urea to the ounce of urine is not diminished. Albumen is regularly present in considerable quantities, casts are somewhat less constant. The patients who have this form of nephritis are apt to exhibit the anæmia and dropsy in a very marked degree and to get worse rapidly.

Chronic nephritis is associated with chronic endocarditis, but apparently not caused by it.

Such an association of chronic nephritis with chronic endocarditis is of very frequent occurrence. Either one of the lesions may be developed the first, either one may be of the most importance.

In all of these cases, while there is much variety in the gross appearance of the kidneys the changes in structure are much the same. The epithelium of the cortex tubes is degenerated; some of the glomeruli are converted into fibrous tissue, in others there is only a growth of the tuft cells; there is a considerable growth of connective tissue in the stroma; the walls of the arteries are thickened. There are, however, two points in which these kidneys differ from each other. The quantity of exudation from the blood vessels

and the rapidity of the changes in the kidney. To these two points of difference correspond the differences in the clinical histories. We may, therefore, for clinical purposes distinguish three forms of chronic nephritis.

1. Chronic nephritis with large and continued exudation of serum from the blood vessels of the kidney into the tubes. The urine is sometimes diminished, sometimes very much increased in quantity. The specific gravity is lowered, often at about 1016. The proportion of urea to the ounce of urine is diminished. The urine constantly contains considerable quantities of albumen and numbers of casts. The patients do badly. Dropsy, anæmia, loss of flesh and strength and chronic uræmia are the regular symptoms.

2. Chronic nephritis with moderate and intermittent exudation from the blood vessels. The urine is more or less increased in quantity, except when the patient has an attack of contraction of the arteries, then it is diminished. The specific gravity is lowered. The proportion of urea to the ounce of urine is diminished. During much of the time no albumen or casts are present, but from time to time when the patient is doing badly in other ways they appear in moderate quantities. These patients usually live for a number of years, slowly getting worse. They are especially liable to attacks of contraction of the arteries with dyspnœa, headache, sleeplessness and convulsions.

3. Chronic nephritis with little or no exudation from the blood vessels, the nephritis advancing very slowly. These kidneys are considered by some authors to be examples of fibroid degeneration, rather than of chronic inflammation. The urine shows no change except that the specific gravity and the proportion of urea from year to year are gradually lowered. Some of the patients never have any renal symptoms. Some of them have attacks of contraction of the arteries. Some of them simply lose some flesh and a great deal of strength and die quietly

*Read in the Section of Surgery and Anatomy at the Fortieth Annual Meeting of the American Medical Association, held at Newport, June, 1889.*

BY CHARLES W. DULLES, M.D.,

SURGEON TO OUT-PATIENTS IN THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, AND IN THE PRESBYTERIAN HOSPITAL, IN PHILADELPHIA.

The subject of properitoneal hernia is so little known in this country that I believe that there have been but three cases with this title recorded by American surgeons. One of these I reported to the Philadelphia Academy of Surgery, December 6, 1886; the second was reported by Dr. Hartley, of New York, in the *N. Y. Medical Record*, about a week later; and the third by Dr. Torrey,

of Brooklyn, in the *Annals of Surgery*, March, 1888.

For this reason I have thought it worth while to bring the subject before this body for consideration and discussion.

In studying the literature of properitoneal hernia I have come to the conclusion that very many cases must have come under the observation of American surgeons who did not classify them as they would have done had they understood them thoroughly. One reason for this conviction rests upon the titles which are at the head of a number of articles upon hernia, as they may be found recorded in the Index Catalogue of the Surgeon-General's Library at Washington. Another rests upon the fact that since the careful studies of this subject by Streubel, Krönlein and Küster in Germany have been published, a considerable number of cases have been specifically recorded in that and in other countries.

It must not be supposed that this fact indicates a mere refinement in diagnosis. It means much more than this; for, before these studies were made, the history of properitoneal hernia was one of unvaried disaster. The diagnosis was, we may say, invariably made on the *post-mortem* table. Since Krönlein pressed his opinions upon the attention of his professional brethren the state of affairs has been very different. Now this form of hernia can not only be diagnosticated during the life of the patient, but it can also be successfully treated.

In a general way a properitoneal hernia may be said to be one which occupies an abnormal position within the abdominal or pelvic wall in front of the peritoneum. Sonnenburg has suggested that the term *præperitoneal* would be more exact. This is true; but we may, I think, hold to the term proposed by Krönlein, lest we introduce confusion by a change which is not important.

A true properitoneal hernia lies between the parietal peritoneum and the overlying mass of muscles, or—when pelvic—the bones. There is also a form of hernia which occupies a position between the planes of the abdominal muscles, which may be called “intermuscular;” and another which lies outside of them and just beneath the skin and superficial fascia. For the last Küster has proposed the term “hernia inguino-superficialis,” and he divides it into three varieties: 1, hernia inguino-superficialis abdominalis; 2, hernia inguino-superficialis cruralis; and 3, hernia inguino-superficialis perinealis; as they occupy respectively the region of the lower abdominal wall, of the thigh, or of the perineum.

The three principal forms of hernia which escape from the usual route of the inguinal canal and the scrotum are: properitoneal, intermuscular and superficial hernia.

I have now collected and studied the histories of thirty-four cases of properitoneal hernia. In

twenty-seven cases the diagnosis was never established until after the death of the patient; in seven cases it was made during life and all of the patients were saved; one without operation and six after operation. This fact alone would justify an attempt to spread the knowledge of this form of hernia.

The history of cases of this sort seems to be that they are, for the most part, originally inguinal herniæ, and often accompanied by an undescended testicle. After occupying the inguinal canal for a certain time, the obstruction offered by the incarcerated testicle, or sometimes by a truss, forces the protrusion, under a strain, out of the canal and into the loose tissue between the peritoneum and the muscles, or between the muscles themselves, or between the whole mass of muscles and the skin and superficial fascia. They usually occupy a position above and parallel to Poupart's ligament, and simulate an encysted hydrocele of the spermatic cord. They are sometimes so large that they overlap Poupart's ligament and hang down over the thigh. Prof. S. D. Gross has recorded a case of this sort. They often extend upward and outward as far as the anterior superior spine of the ilium. On investigation they can often be grasped in the hand through the abdominal wall and felt as distinct and movable tumors.

The treatment of properitoneal hernia is usually by a cutting operation. I have found the record of only one case which was successfully treated by taxis; and my investigations lead me to the belief that this is the most dangerous way to treat it. The most natural plan is to make a free incision, similar to that for incarcerated inguinal hernia, and to follow this up with whatever dissection is necessary to restore the bowel to the cavity of the abdomen.

Probably the best method of operating would be to make an incision through the linea alba, as if for a laparotomy, and to draw the intestine back from the hernial sac, instead of pushing it back as in the usual operation of herniotomy. By this means there ought to be no danger of a reduction *en masse*, which is the most dangerous thing which can happen in such operations.

For further information in regard to this whole subject I cannot do better than to refer you to the writings of Streubel, Krönlein, Trendelenberg and Küster, of which—with others—I have given a list in a paper published in the *Medical News*, January 22, 1887, and to the excellent paper by Drs. Hartley and Torrey to which I have referred above.

4101 Walnut St.

DR. LONG, U. S. Marine-Hosp. Service, said that he had operated for radical cure twenty-four times in cases of reducible hernia, with two failures to cure. There had been no fatalities or even apparent danger to life. He had had some experience that might interest the members of the

Section. In one of his cases he had operated and discharged the patient two months subsequently apparently cured. This patient was readmitted to hospital eight months after with pneumonia and died. The speaker made a careful dissection of the hernia after the death of the patient. The operation had been a modified Czerny's in which the stump had been sewed up between the pillars of the ring, hoping to secure union and have the stump act as a plug. He found on dissection that there was union between the pillars throughout the length of the opening, but no sign of the stump enclosed. On the inside he found a small cone-shaped (with the top of the cone cut off) portion of the peritoneum resting against the inner surface of the ring. The top of the section of cone was nearly  $\frac{1}{4}$  of an inch thick, and certainly of itself offered considerable resistance. Dr. Long thought favorably of McBurney's operation and did not think, in the light of experience, that sewing the stump of the amputated sac in the ring was of any advantage whatever. In his twenty-third case he met with a condition of things that was peculiar. There was no superfluous fat and the sac was easily reached, but the adhesions between it and the tunica vaginalis were so intimate that it seemed impossible to separate them. During the operation he unwittingly opened the cavity of the tunica vaginalis, and subsequently opened the sac, thinking by inserting his finger he could more easily effect a separation. This was found impossible, and the wound in the sac was closed and the mass returned, and the pillars closed. The external wound was left open, hoping to reinforce the parts by cicatricial tissue. He hoped for a good result in this case in spite of the difficulties. As to the matter of particular operations, choice of sutures and kind of stitches, they were matters to be relegated to the choice, fancy or experience of the operator. The speaker said that he had experimented with varieties of catgut. He formerly used the catgut preserved in juniper oil because of its great pliability, but found that it would undergo solution in from four to six days, while that prepared with chromic acid, No. 3 size, will hold for from twelve to eighteen days before undergoing solution, and by that time we will have accomplished all that may be expected from sutures. There is no question as to the advisability of curing hernia by surgical measures.

#### PAINFUL MUSCULAR SPASMS AFTER FRACTURE PERFECTLY CONTROLLED BY SULFONAL.

BY EDMUND ANDREWS, M.D.,

SENIOR SURGEON OF MERCY HOSPITAL, ETC., CHICAGO.

The ordinary anodynes and antispasmodics do not give us full satisfaction in the muscular

spasms following fractures. It is true that they help somewhat, yet even under the influence of morphine the patient, though quiet when awake, is aroused from his sleep by repeated painful contractions, which continue for days to be a serious source of distress.

In three such cases I have given sulfonal in doses of 15 grs., repeated if necessary, say once in four to six hours. In each case the medicine has stopped the spasmodic twitches completely, giving the patient a wonderful relief. If further experience confirms this result, sulfonal will be a great boon to surgeons and to their patients.

There are other varieties of reflex spasm which may perhaps be relieved by the same remedy. For instance, in hip disease, the inflamed head of the femur provokes frequent nocturnal spasms of the adjacent muscles, causing the patient to awake with a scream. Extension apparatus generally controls this, but in many instances an adjuvant is needed for a time, and sulfonal may prove to be as effective for this purpose as it is in fractures.

It is probable that numerous other varieties of reflex spasm may be equally benefited by the remedy, so that investigations ought to be made in this direction.

No. 6 Sixteenth St., Chicago.

## MEDICAL PROGRESS.

**CHLOROFORM ACCIDENTS.**—Apropos of a recent discussion in the Paris Académie de Médecine, PROF. DASTRE classifies the causes of fatal accidents resulting from the administration of chloroform as follows: Primary syncope, respiratory or cardiac; secondary syncope; toxic apnoea. In the first class death results from the first inhalations (initial shock); this occurs from reflex cardiac syncope in nervous, impressionable individuals weakened by suppuration or hæmorrhages, or in individuals otherwise healthy who suffer from irregularity of the heart's action (in animals with those which exhibit habitual cardiac irregularity, as the dog), or they arise from reflex apnoea under analogous conditions. In the second class (secondary or bulbar syncope) narcotism is more advanced; the heart's action may be arrested suddenly or gradually; the arrest of respiration may be slow and progressive or sudden from tetanic spasm of the glottis. The third class of cases comprises those of fatal intoxication in which the agent has been administered too freely or for too long a time, and the anatomical elements, particularly the nerve elements, have lost their vitality. In this form of chloroform poisoning there is a destruction of mechanism which seems to involve derangement of the entire respiratory apparatus.

The real danger in the administration of chlo-

roform is from the effects produced upon the heart and not from those upon the respiratory organs. In the case of heart failure we are practically without resource, while in the case of respiratory insufficiency we have a remedy in artificial respiration. In opposition to the generally accepted opinion, the arrest of the heart's action is a phenomenon of excitation and not of paralysis or paresis. This is true of at least four out of five cases.

As a remedy for chloroform intoxication Prof. Dastre proposes a mixed form of chloroform administration. Inasmuch as in the majority of cases it is the stimulation of the inhibitory cardiac apparatus that is concerned, section of the two vagi nerves would constitute the theoretical remedy. This being inadmissible, we have still a practical and delicate means of arriving at the same result, *i. e.*, the administration of atropin. This is really equivalent to section of the vagus, which destroys the excitability of the cardiac filaments as well as their bulbar nucleus. Atropin, however, should not be employed alone on account of its excitative tendencies, which may be obviated by the concomitant administration of its antidote, morphine. The action of the combination of atropin, morphine and chloroform has been experimentally tested in the case of dogs. The dog is infinitely more subject to chloroform accidents than is man. In the laboratory of Sorbonne one dog in three was lost by accident. During the last ten years all the dogs have been anesthetized by the mixed method, and in hundreds of cases of narcosis there has not been a single death. The mode of procedure is as follows: Ten minutes before the operation a subcutaneous injection is made of a solution containing 2 centigrams of muriate of morphia and 2 milligrams of sulphate of atropia per cubic centimetre. Of this half a cubic centimetre per kilogram of the animal's weight is used. The administration of chloroform is then begun, 2 or 3 grams being sufficient to produce a perfect anaesthesia lasting two hours—a much less quantity than would otherwise be required, while the economy in its use greatly diminishes the danger of fatal results. This mixed method has also been used in human surgery, particularly by M. Aubert and his surgical colleagues of Lyons, who employ the following formula: An injection is made from fifteen to thirty minutes before the operation of 1½ cubic centimetre of the following solution:

Muriate of morphia . . . . .	10 centigr.
Sulphate of atropia . . . . .	5 milligr.
Distilled water, . . . . .	10 grams.

M. Aubert gave an account of his experience with the method (Soc. Biol., April 21, 1883) in these terms: "I know of nothing more desirable or practicable. The advantages are the following: 1, safety; 2, the great rapidity with which sleep

is produced; 3, the absolute repose of the patient; 4, the quick return of consciousness; 5, the absence of unpleasant sequelæ such as vomiting. Some of my colleagues have at my suggestion employed the method, and M. Gayet particularly recommends it in ophthalmological surgery." The number of instances of its employment now mounts up (1887) into the thousands, and without the occurrence of a single accident.—*La Semaine Médicale*, August 28, 1889.

**THE TREATMENT OF OZÆNA WITH GLYCERINE.**—At a recent meeting of the Society of Military Surgeons in Vienna, DR. SIDLO strongly recommended the treatment of ozæna with glycerine. His method consists in daily washing out the nasal cavity with a 2 per cent. solution of chloride of potassium, to which 10 per cent. of glycerine has been added. This is followed up with the insertion of rolls of cotton soaked in a mixture of one part of glycerine and three parts of water, the tampons being allowed to remain in place for an hour at a time. Using this method, he claims good success in the management of ozæna. The method requires some weeks to effect a cure; but no one who has treated ozæna often will think a few weeks too long to devote to any method which is likely to be successful. The one proposed by Dr. Sidlo is so simple, and apparently so rational, that it certainly seems worthy of further trial, and if other medical men can cure such cases as he has cured in this way, it will be a very useful addition to our therapeutic resources.—*Medical and Surgical Reporter*.

**ANTIPYRIN IN DIABETES.**—DRS. GLEY and GERMAIN SÉE report a number of cases of artificial glycosuria in dogs, in which the good effects of antipyrin in this affection were well illustrated. To a dog passing 13 grams of sugar a day, one gram of antipyrin per diem was given for eight days, at the end of which time the amount of sugar had fallen to eleven grams. At another time the quantity of sugar was reduced by the same means from about ten to less than six grams. Dr. Sée has also employed the drug in the treatment of glycosuria in the human subject with good results. Lépine and Porteret have shown that antipyrin has the effect of retarding the transformation of glycogen in the liver and muscles into glucose. M. Huchard has previously related several cases of polyuria and glycosuria, in which the exhibition of antipyrin was followed by good results. The latter author believes that this drug has a special utility in bulbar neurosis, among which he classes diabetes, polyuria and exophthalmic goitre.—*Revue Générale de Clinique et de Thérapeutique*.—*The Medical Record*.

**FOR THE RELIEF OF CORYZA.**—DR. KÖHLER

recommends inhalations of camphor as affording great relief in the early stages of an acute coryza. He puts one teaspoonful of powdered camphor in a rather deep vessel, half fills the latter with boiling water, and covers it with a paper cone. The end of this cone is torn off so as to just fit the nose. The warm camphor-laden vapor is then inhaled through the nose, not the mouth, for a period of from ten to fifteen minutes. This procedure is repeated every four or five hours. After the third inhalation, even the most stubborn catarrh, says Dr. Köhler, will be found to have completely disappeared. Any laryngeal catarrh, which may be present at the same time, will be found to be considerably benefited by the action of the camphor vapor.—*Zeitschrift für Therapie*.—*The Medical Record*.

**URETHRAL VEGETATION REMOVED BY THE AID OF THE ENDOSCOPE.**—DR. F. R. EVERSOLE, of St. Louis, reports a case in which, by the aid of the endoscope, he diagnosed the presence of a venereal growth in the urethra, four inches from the meatus, and successfully removed it with the curette. The application of a 10 per cent. solution of cocaine was useful in checking the hæmorrhage. He also finds the endoscope useful in cases where there is great difficulty in passing bougies through tight strictures. The use of cocaine makes the introduction of the endoscope comparatively painless.—*St. Louis Polyclinic*, August, 1889.

**ATROPHY OF THE OPTIC NERVE.**—DR. WIGLESWORTH finds that optic nerve atrophy is frequently met with in general paralysis usually as a late symptom, though it sometimes occurs early. He narrates a case in which the optic atrophy was the first sign of the disease preceding by some time the mental symptoms. Dr. Percy Smith and Dr. Yellowlees cite similar cases.—*Brit. Med. Jour.*, Sept. 21, 1889.

**SUSPENSION TREATMENT.**—DR. A. B. SHAW, of St. Louis, gives the results obtained in three cases by this method. The treatment extended over a period of about eight weeks, with sittings every two to four days. The tractile force used, as measured in pounds by a spring balance, varied from 50 to 128. Two cases of tabes dorsalis and one of cerebro-spinal sclerosis were treated; the patients were all aged, respectively, 32, 66 and 47 years. The results obtained were extremely satisfactory in all instances.—*Weekly Medical Review*, Aug. 31, 1889.

**DIGITALIS IN PNEUMONIA.**—M. PETRESCH, of Bucharest, claims that pneumonia can be aborted in its early stages by giving large doses of digitalis, e.g., 4 to 8 grams of the leaves in infusion daily.

SATURDAY, OCTOBER 19, 1889.

PUERPERAL ECLAMPSIA.

Of late, much affectation of unbelief in the so-called urinæmic origin of the very large majority of cases of puerperal eclampsia has crept insidiously into the literature of the subject. This fact is particularly apparent in recent American contributions. For example, in the second volume of the *American System of Obstetrics*, PARVIN gives a most confused account of the causation of this disorder, while HIRST, the editor of the *System*, asserts that "very little is known about the etiology of the disease." We have ventured to characterize this agnostic state of mind as an affectation, since these and all other authorities base the entire prophylaxis and very much of the therapy upon the notion that in the very large majority of cases, eclampsia is the expression of a toxæmia, conditioned upon functional or organic disease of the kidneys, or upon the obstruction to the flow of urine through the ureters. Thus all authorities urge the qualitative and quantitative examination of the urine in every case of pregnancy. In event of pathological albuminuria, or in case of any other significant alteration in the quality or quantity of the urine, the mandatory indications for preventive treatment are fulfilled only by the rigorous restriction of diet to milk, the systematic use of the hot water bath, and the prompt induction of premature labor when other means fail to relieve the symptoms. All these preventive measures indicate a practical faith in the theory of renal inadequacy that belies the confession of ignorance just mentioned.

It has been well said that it is an anachronism to doubt the identity of puerperal fever with the infectious wound-diseases. The same remark is applicable to unbelief in the doctrine of the renal origin of puerperal eclampsia in the very large majority of cases. For CARL BRAUN (1857) demonstrated the dominant influence, as a causal factor, of acute renal inadequacy, while HARBERTSMA (1871) has shown the occasional etiological significance of obstruction to the flow of urine through the ureters. These teachings to-day rest on evidence, cumulative from observation and experiment, that is conclusive, and that in kind and degree closely resembles the proof of the Semmelweis theory of puerperal fever.

The idea conceived by the individual practitioner as to the causation of puerperal convulsions is of the utmost moment to his patient, since upon this conception must depend all treatment, preventive and curative. Under all these conditions, has one the right to "count it a bondage to fix a belief," or to affect "free will in thinking?"

Doubtless some of the confusion on the subject is due to the use of the term eclampsia as indicative of a disease, and not merely as the name of a symptom. Perhaps it would be better to designate the condition in the concrete case more exactly by speaking of the eclampsia of Bright's disease, of urinary absorption, of acute yellow atrophy of the liver, and the like. Then, too, it is absolutely necessary to exclude from the notion of puerperal eclampsia, and to eliminate from the record of cases, convulsions due to epilepsy, hysteria, tetanus, meningitis, cerebral tumors, acute anæmia, and the like. Convulsions owing to such causes obviously have no relation to the morbid state under discussion.

As before remarked, the Brahm-Halbertsma doctrine of eclampsia does not include *all* cases, although it is adequately explanatory of *nearly* all cases. The urinæmic theory, as presented above, is not an universal proposition.

STUMPF (1886) succeeded in the demonstration of acetone in the distilled urine of a few eclampics, and of sugar in the urine of a few others. He is of the opinion that, under abnormal decomposition processes, there is released a nitrogen-free, toxic substance—possibly acetone or an allied body with the same reactions—which, during excretion, irritates the kidneys to the point of nephritis, destroys the coloring matter of the

blood, alters the activity of the liver cells, causes the presence of sugar, the destruction of the hepatic parenchyma to the degree of acute yellow atrophy with the production of tyrosin and leucin, and finally, by irritation of the encephalon, determines coma and convulsions (Winckel). What may be the cause of these abnormal decomposition processes, whether it be an agent of infection, exogenous in origin, or whether it arise within the body of the foetus, Stumpf does not pretend to say. In this connection the cases of eclampsia associated with hæmorrhagic hepatitis, very lately reported by GUSTAV BRAUN, are of extraordinary interest. There are not lacking those that regard many forms of the nephritis of pregnancy as the expression of infection. They seek to explain in this way the remarkable cases of Stumpf and Gustav Braun. It has been asserted that microorganisms may enter the body through the atrium of the intestinal tract, circulate in the blood, determine destruction of tissue and capillary embolism in the kidneys, liver and other viscera, or produce toxic effects through their leucomaines. In passing it may be remarked that these observers allow bacteria to play a closely similar rôle in nephritis as it occurs in men and non-gravid women. For the present, however, the cases are too few in number and the facts altogether too meager to admit of generalization. But enough has been learned to stimulate research, to necessitate more exact anatomical diagnosis, to compel more thorough chemical examination of the fluids of the living and of the dead body, and, finally, the claims of the bacteriologist demand closest attention.

#### PHYSIOLOGICAL DIFFICULTIES AT THE CLARK UNIVERSITY.

From the *Worcester Gazette* we learn that the curators of the Clark University have encountered unforeseen difficulties in the way of obtaining physiological and other trained teachers from German universities. The curators had desired to secure certain young Germans, highly trained according to the modern methods, who would be willing for a limited number of years to teach at the new university, in the expectation that the way would be left open for these men to return to their home university without detriment to their future at the institution of their choice.

There was no paucity of such young professors who were willing to come to America temporarily to teach at Worcester and other places, but the governing powers at their universities, as a rule, declined to look favorably upon such temporary absences. They have declined to grant any such furloughs. A few of those German instructors may come over, but it will be virtual to an expatriation or exmatriation from their home institutions.

It would seem reasonable, from our American point of view, to expect that some German university would seize upon the opportunity as an opening for the extension of its influence, as if invited to establish a colonial graft of the higher methods of learning, but no, they are content in themselves, and have nothing to spare to others at a distance. It would seem as if the liberalizing tendencies of the present day had stopped short at the gates of the universities. But the American skirts are not clear, and it will not comport with the existing conditions of our statute books to proffer too much criticism. Our laws have not been so framed that we can promise the warmest kind of welcome to educators who may decide to come to our shores. For who can promise the latter that they will not have to run the gauntlet of the alien-labor contract law? It is a hard saying, but a fact, nevertheless, that here are two of the most advanced of modern nations, conspiring together, for differing ends of policy or politics, to put a stumbling-block in the way of the diffusion of an advanced education. These policies of government are wrong and cannot persist: for if there be no common ground between nations in a question of education, there should be no comity in any relation. Of all the people on the face of the globe who should have a free passport to come and go at their good pleasure, the scholarly teacher and the teachable scholar are the ones who should be favored. They, together with the scientific explorer, should be accorded the fullest international liberty and every degree of welcome. This experience of disappointment at the Clark University merits the profession's attention, for the reason that medicine has much to expect from the preparations that have there been made for the development of physiological and psychological studies to an extent that has not been reached at any other institution in this country.

In the interest of profound medical research, it is to be hoped that this disappointment of the curators will be only temporary.

#### THE RUSH MONUMENT.

Our readers will find in the present number of *THE JOURNAL*, under the head of "Domestic Correspondence," a letter from SECRETARY ATKINSON calling the attention of the Secretaries of the various medical societies in the United States to the Resolution adopted by the Association at its last annual meeting at Newport.

We sincerely hope that every society will regard that communication as a personal appeal, and that at once and everywhere efficient action will be taken to secure at an early day the accomplishment of the desired result. Let the officers of every medical organization interest themselves in this matter, and be sure that their individual work is well done.

Among the benefactors of mankind whose deeds are worthy of special remembrance there are none more conspicuous than are found in the medical profession, and among the names of medical men, there is no one which we more delight to honor than the name of BENJAMIN RUSH.

#### EDITORIAL NOTES.

##### HOME.

**THE DETROIT ACADEMY OF MEDICINE.**—The following were elected officers for the ensuing year at the annual meeting held last month: President, Dr. Henry A. Cleland; Vice-President, Dr. F. C. Heath; Secretary, Dr. Wm. B. Sprague; Treasurer, Dr. W. J. Cree.

**THE PRICE OF QUININE** has again fallen and, consequently, the large holders thereof are suffering from an attack closely approximating ague.

**DR. D. D. RICHARDSON**, of Philadelphia, has been elected Superintendent of the Diamond State Insane Asylum, Farnhurst, Del.

**THE MEETING OF THE AMERICAN ACADEMY OF MEDICINE.**—The annual meeting of this medical organization, of which Dr. Leartus Connor is President and Dr. R. J. Dunglison is Secretary, will convene in Chicago on November 13th and 14th. The academy is composed of men who have been graduated from literary colleges, and it has for one of its purposes the securing of like

preliminary education by students previous to their entrance upon the study of medicine. From the well-known ability of its active members and the number of valuable papers to be presented, we may confidently anticipate a most interesting meeting.

**DR. THOMAS A. DAVIE**, surgeon for the Northern Pacific Railroad Company, died recently at Tacoma of typhoid fever.

**CALIFORNIA STATE MEDICAL SOCIETY.**—*The Pacific Medical Journal* says: It will be remembered that at the last meeting of the State Medical Society it was enacted that one qualification necessary for membership should be continuous membership in the regular local medical society. This action has been widely discussed and most favorably commented upon by the Eastern medical press. It is looked upon as a capital method for cementing the profession, binding together the various medical organizations and encouraging them to work in harmony and effectually.

**WHAT WILL YOU DO?**—The next three months afford a favorable opportunity to enlarge the subscription list of *THE JOURNAL*. It is within the power of each of our readers to secure one new subscriber. Every member of the American Medical Association is a stockholder in *THE JOURNAL* and, as such, should use every effort to increase its circulation and influence. To those who will get up clubs we will make special terms. Will each of our readers write us, sending a list of physicians to whom sample copies should be sent? Be in earnest in this matter. The larger subscription list we can obtain before the close of the year, the better *Journal* we can give you for 1890. What will *you* do?

**SPECIAL NOTICE.**—The American Academy of Medicine is endeavoring to make as complete a list as possible of the Alumni of Literary Colleges in the United States and Canada, who have received the degree of M.D. All recipients of both degrees, literary and medical, are requested to forward their names at once to Dr. R. J. Dunglison, Secretary, 814 N. 16th street, Philadelphia, Pa.

**THE AMERICAN RHINOLOGICAL ASSOCIATION** closed its seventh annual session at Chicago last week. The new officers elected are; President, Dr. A. G. Hobbs, Atlanta, Ga.; First Vice-Presi-

dent, Dr. A. B. Thrasher, Cincinnati; Second Vice-President, Dr. E. R. Lewis, Indianapolis; Secretary and Treasurer, Dr. R. S. Knode, Omaha; Librarian, Dr. John North, Toledo; Member of Council, Dr. C. H. von Klein, Dayton, O.

## FOREIGN.

THE great amphitheatre of the School of Medicine at Paris was destroyed by fire last week.

DR. LAUDER BRUNTON will pay a visit to India to test the results of the Hyderabad Chloroform Commission.

THE GERMAN DERMATOLOGICAL SOCIETY will hold its next annual meeting at Berlin in connection with the International Medical Congress.

DR. KARL FRANKEL will fill the new chair of Hygiene and Bacteriology in the University of Königsberg.

QUEEN'S COLLEGE, BIRMINGHAM.—A new theatre has been recently fitted up for lectures on medicine, etc., the former medical school being now reserved for anatomy.

AN ANTI-VACCINATION CONGRESS was recently held in Paris. The President, M. Boeus, a Belgian, stated that small-pox is not so fatal as is believed, also that the use of candles, instead of gas or lamps, which give a strong light, prevents small-pox patients from being marked.

THE DEPOPULATION OF FRANCE is causing the French legislators a great deal of anxiety. A correspondent of the *British Medical Journal* suggests that it would be wise to move for a strict inquiry into French baby-farming, and adopt energetic measures to prevent the loss of infant life attending this system.

THE ADMISSION OF WOMEN TO THE BELFAST MEDICAL SCHOOL.—The *British Medical Journal* says: An application was recently made by three young ladies to the medical professors of the Queen's College, Belfast, to have the medical classes thrown open to women. The Arts classes of the College were opened to women some years ago with results in every way satisfactory, and we understand that the above application has been favorably entertained by the medical professors. The next question will be the opening to women of the medical practice of the various hospitals, especially the chief teaching institution in Belfast, the Royal Hospital. It is believed, however, that

no difficulty is likely to arise on this side. Experience has shown that young men and young women can be taught conjointly at the bedside without inconvenience.

CHOLERA IN ASIATIC TURKEY.—Bagdad and Bussorah have, according to a correspondent of the London *Times*, been visited by an epidemic of cholera. The disease was first noticed in obscure inland spots, whence it spread to the port of Bussorah, near the head of the Gulf of Persia. From the first, the Ottoman Government left nothing undone in the way of quarantine to prevent it spreading up the Tigris, but all efforts proved unavailing. At Bagdad a severe outbreak has occurred, many dying daily; in the absence of systematic registration, it is impossible to say how many.

NATIVE WOMEN IN THE MEDICAL SCHOOLS OF INDIA.—The *Provincial Medical Journal* says: At the present moment there are some 200 native women studying medicine in the medical schools at Bombay, Calcutta, Lahore, Madras, Hyderabad and Agra, which is the last one to open a class to the sex. Some will take Indian University degrees, some will come here, or go to the Continental or the American schools, to carry their education as far as possible, though the majority will never proceed further with their studies than to be classified as "hospital assistants." At the outset of the movement it was difficult to find Indian girls sufficiently bold to break through the traditions of centuries, and come forward to adopt the profession; but now there is almost an *embarras du choix*, and rigid supervision is exercised in the selection of those only who are intellectually and physically equal to the training. The National Association now has eleven fully qualified lady doctors practicing in various parts, and of these five were trained in England and six in India. It now only permits ladies to designate themselves "doctors" if their education has been sufficient to permit them to be registered under the Medical Acts in force here, and gives to less highly qualified women the titles of "Female Assistant Surgeon," or "Female Hospital Assistant." It is pleasant testimony to hear that the strictly "unsectarian" scope of the National Association did not prevent ladies of the various medical and Zenana missions from giving it all the help and counsel in their power.

## TOPICS OF THE WEEK.

## THE LATE SESSION OF THE NEW YORK STATE MEDICAL ASSOCIATION.

Under the above heading we quote an editorial from the *Medical Record* of October 5, as follows :

The recent session of this Association was characterized by an exceptionally large attendance, and much manifest interest in the proceedings. The topics discussed made a home-like appeal to the general practitioner, whose zeal is in the direction of the "first care;" they were practical, well selected, exhaustive and scholarly. Many new men, destined to make their mark, surprised both themselves and others with the applause gained by their ambitious endeavors and the results of their work. There were some disappointments, owing to the failure of a rather crowded programme and the absence of certain advertised participants, but, on the whole, these drawbacks were more than compensated for by the eagerness of volunteers to fill the gaps, so that there was no real dearth of substantial material.

The set discussions on the collective-investigation plan, which seem to have come to grief across the ocean, were both satisfactory and successful. The themes selected, such as "Tubal Pregnancy," the "Treatment of Hernia," and the "New Hypnotics," were timely and well treated. We may say, in fact, that they were exceedingly well handled, and so far as the detailed questions were concerned, assigned to those who were able to speak by authority. There were very little crudities of thought or looseness of statement, but, on the contrary, much honesty of investigation, some skeptical interrogation, and a deal of logical candor.

Much as we have deplored the Code schism, we are fain to acknowledge that, when families become too large, the component individuals may gain in energy and benefaction by separating for the purpose of house-keeping on their own account; at all events, in the present instance, sympathy appears to drift somewhat toward the young couple, especially when zeal and honest endeavor go hand in hand. Certainly, if the Association aim for influence and additions to our stock of knowledge, not only the profession but the public at large cannot fail to be benefited—the field is large, the harvest ripe, and the laborers none too many.

## THE HISTORY OF ORTHOPEDIC SURGERY IN AMERICA

From the very able and interesting address of the President, DR. E. H. BRADFORD, delivered in Boston, September 17, 1889, at the third annual meeting of the American Orthopedic Association, and reported in the *Boston Medical and Surgical Journal*, we present the following :

The history of orthopedic surgery in America can never be thoroughly written, as the earlier facilities for presenting cases and recording methods were necessarily imperfect in a new country. The earlier American bibliography, prior to 1860, which, through the kindness of Dr. Billings, has been copied for me from the catalogue

of the Army Medical Library, shows not only much that is of interest, but indicates by what is implied as much as by what is published, that much excellent work was done which escapes the annalist.

The first triumph in orthopedic surgery in America is the classical operation by Rhea Barton (*North American Medical and Surgical Journal*, 1827, p. 279), the founder of osteotomy for correction of deformity, as McDowell is the founder of ovariectomy.

Physick's Fixation Hip Splint, described in 1831; Chase's paper on the "Treatment of Club Foot Without Tenotomy" (*American Journal of Medical Sciences*), 1841; Mütter's work on "Club Foot" in 1845—all indicate the intelligent interest taken in the subject. Excision of the hip was first performed in this country by Dr. Wilcox, of Eastern Pennsylvania, as early as 1849.

The stimulus of Stromeyer's achievements was quickly felt in America, and tenotomies were done by Rogers (1834), Dickson (1835) and Detmold (1837). To the latter belongs the credit of the first published tenotomy, the tenotomies of the two former surgeons not having been recorded. Detmold also acted *ex cathedra*, as it were, for he was fresh from the teachings of Stromeyer. The interest taken by general surgeons of the time in orthopedic surgery is indicated by the remarks of Valentine Mott, as quoted by Mütter, of Philadelphia, and by the well-known work on "Orthopedic Surgery," by Dr. Henry J. Bigelow, published in 1845, and which to-day is a model of excellence, and one of the best of publications to illustrate the French school of orthopedic surgery, the dominant school of the time. . . . Speaking of the history of orthopedic surgery in New England he says :

Dr. Buckminster Brown has been kind enough to write for me the following outline of the history of orthopedic surgery in New England, which I quote in full :

"The history of orthopedic surgery in New England commenced in 1838, when Dr. John Ball Brown, of Boston, treated nine cases of spinal disease and curvature. Dr. Brown was for several years associate surgeon with Dr. John C. Warren, and afterwards consulting surgeon at the Massachusetts General Hospital. For some years previous to the above date he had given much attention to this class of complaints. In 1839 Dr. Brown received from Paris a copy of a publication of M. Bonvier, in which he describes the operation for the section of tendons in club foot devised by Delpech, together with the introduction by Stromeyer of subcutaneous tenotomy, his own (M. Bonvier's) modification of this method. He also received at the same time the apparatus employed in the after-treatment. Dr. Brown at once decided to perform this operation and to pursue the method of treatment described.

"On February 21, 1839, he did the operation on a little girl 4 or 5 years of age, who had talipes varus. The treatment was successful. So far as was known to Dr. Brown, this was the first time that subcutaneous tenotomy had been done in America. He afterwards learned it had been done once previously by Dr. Detmold, of New York. Dr. W. J. Little, of London, about this time published his first work on "Club Foot and Analogous

Distortions," and this was a great assistance to the American pioneer.

"The various French treatises on this and kindred subjects by Guérin, Bouvier, Chassignac and others were also welcome aid during the earlier years. He imported from Europe various instruments and drawings of apparatus, invented many and modified others.

"From the date above named Dr. Brown had an extensive experience in this branch of surgery, and his reputation spread widely. Patients, not only from the neighboring States, but from the South and from the West, and even from the Sandwich Islands, journeyed to Boston for the purpose of being placed under his care. In 1849 he opened, in a house hired for the purpose, a small hospital for the treatment of orthopedic cases. Dr. Brown continued in the practice of orthopedic surgery until his death, which occurred in 1862.

"Dr. Brown's treatment of talipes was essentially modelled on that of Little and Bouvier. In lateral curvature he adopted, to a certain extent, the course pursued by Jules Guérin, with modifications and improvements of his own; and in spinal caries fixation was the point aimed at.

"In 1846 Dr. Buckminster Brown returned from Europe, where he had followed the practice of Little, Stromeyer, Guérin and others. He immediately commenced practice in his profession, at first combining the orthopedic branch with general practice, and finally confining himself to the former. From this date to the present, he has from time to time published some of the results obtained from his practice and experience.

"In 1861 Dr. Buckminster Brown took charge of a ward in the Samaritan Hospital, for treatment of deformities."

The Children's Hospital in Boston, opened in 1866, though not an orthopedic institution, necessarily demanded treatment for cases of this sort, and has developed in this direction to such an extent that its orthopedic clinic may be said to be one of its most prominent features.

The increase of interest in this branch of surgery is marked in a practical way by the foundation of special hospitals. On May 1, 1863, the Hospital for Ruptured and Crippled, of New York, was opened by Dr. Knight, and is now one of the largest hospitals of its kind in existence. In 1866, an Orthopedic Dispensary was opened in New York, by Dr. C. F. Taylor. In 1873 it was enlarged into a hospital. Dr. C. F. Taylor was appointed consulting physician, in 1868, to St. Luke's Hospital, and in 1872, Dr. Shaffer was appointed visiting consulting surgeon there. The interest in the treatment of deformities by Dr. J. K. Mitchell, of Philadelphia, was active, and led to the establishment of an orthopedic hospital in that city.

#### LOCAL MEDICAL SOCIETIES.

We transcribe from the *Atlanta Medical and Surgical Journal* for October the following editorial:

With the advent of cooler weather, the time has arrived when medical societies all over the land are buckling on the armor and preparing for their winter's work.

The hot months, relaxing alike to the mental and physical energies, have caused a cessation of society work for a time. But now that the profession is settling down once more to its regular labors, the demands of the local medical societies upon the recognition and attention of the medical man should not pass unheeded. It is to be regretted that the advantages of such associations for united professional work are not more fully recognized, or if recognized, that such recognition is not more universally translated into practice. That medical societies are the most potent instrumentalities for the advancement of medical science is a fact that cannot be gainsaid by any observant man. A moment's thought will convince any one that the best results that are obtained in this direction are almost invariably wrought out under the stimulating influence of the contact of mind with mind. The practitioner is thereby lifted out of the ruts into which every one is so liable to fall when working by himself alone, and he learns that there are other works of practice and other lines of thought outside of those to which he has become accustomed. The tendency of society work is to broaden a man's views of medical matters, to enlarge his field of vision, and thereby to make his daily practice more satisfactory to himself and more beneficial to his patients.

These are facts which are too patent to admit of argument. Yet there are many men of good standing in the profession who are never seen in the medical society. Why this should be so it is difficult to understand. It is true that the arduous duties of a large practice leave but little leisure for anything else; yet the men who have large practices are the very ones who will derive the most benefit to themselves by occasionally stepping aside from the practical application of their wide experience to compare their views with those of other men, and to avoid thereby the tendency to routine which is inseparable from unremitting professional toil. Moreover, the social element which always enters to a greater or lesser extent into all societies is promotive of a friendly professional feeling and a proper *esprit de corps*, which is apt to drop out of sight altogether when every man is working on his own independent schedule.

To the younger portion of the profession the value of the medical society cannot be overestimated. There he has the opportunity to avail himself of the experience of older and wiser men and to learn lessons in practice which cannot be learned from the generalizations of his text-books. Next to actual individual experience there is no school so valuable to the young practitioner as the medical society.

We would therefore urge upon our readers the desirability of the formation and support of organizations of this kind. In thinly settled districts two or more counties might advantageously unite and hold monthly meetings at some accessible point. In the cities and larger towns where societies already exist we would urge a more general membership and a more frequent attendance of meetings. The result of such a course would soon be felt in an elevation of the tone of the profession, a promotion of scientific and accurate medical knowledge, and a better ethical spirit everywhere. Petty jealousies and animosities would disappear, knowledge of medical science would be promoted, and the profession would be brought nearer to that plane which we all recognize as alone worthy of a noble and lofty calling.

## PRACTICAL NOTES.

## SALICYLIC ACID IN MALIGNANT SCARLATINA.

DR. SHAKOWSKI has administered salicylic acid with the greatest success in 125 cases of grave scarlatina occurring in children, the mortality being reduced to  $3\frac{1}{2}$  per cent. Ordinarily his method of administration was in the form of a mixture consisting of one part of salicylic acid to seventy-five parts of water and thirty parts of syrup of orange peel, a teaspoonful of this being given every hour during the day and every two hours during the night. He writes that under the influence of this remedy the temperature is rapidly reduced, in certain cases, even at the end of forty-eight hours, the temperature falling four degrees. Habitually all traces of fever disappear after the tenth day of the disease. Nevertheless, the author advises to prolong the treatment for some time longer than this in progressively decreasing doses, so as to avoid any danger of relapse. Through the use of this remedy the author believes that he has avoided the most serious complications of scarlatina, such as uræmia, anasarca and diphtheria. He claims that this medication will only be ineffectual when given too late—that is, after the fourth day of the disease, or when there exists some grave chronic complication.—*Revue mensuel des Mal de l'Enfance*.—*The Therapeutic Analyst*.

## SOME OF THE NEW SKIN REMEDIES.

BULKLEY stated in his address as chairman of the Section on Dermatology, at the Newport meeting, that resorcin and ichthyol have not fulfilled the expectations incited by Anno. They are not indifferent, but their use is restricted. The thorough and continuous use of a zinc ointment, containing 20 grs. each of salicylic acid and ichthyol, produces excellent results in infantile eczema. Resorcin is a parasiticide, useful in ringworm, seborrhœic eczema and psoriasis. It is useful in acne (5 per cent. in alcohol and water) to check the oily secretions. Too much is irritating and discolors the epidermis.

Lanolin has but limited uses also. It will not do alone as a basis for ointments; 25 per cent., with other fats, keeps the skin soft and pliable. It has been pushed by the trade, but is little used by dermatologists.

The New York Dermatological Society has taken strong action against making vaseline, cosmoline, etc., the basis of ointments in the coming revision of the Pharmacopœia. They are good for lubricants in scaly skin troubles, and to carry carbolic acid as an antipruritic. Even albolene is too soft for a protective, and Hebra's diachylon ointment is still at the head. Bulkley prefers the unguentum aquæ rosæ—almond oil, spermaceti,

white wax and water—to all others in compounding prescriptions.

Salicylic acid maintains its reputation, and has come to stay; 3 per cent. in hair tonics where there is an oily scalp; 10 to 20 per cent. in alcohol and water as an efficient parasiticide; a drachm each of oxide of zinc and salicylic acid to the oz. of starch, in checking excessive perspiration of the axilla and feet; these are among the uses of salicylic acid.

Anthrabin, in a 10 per cent. ointment, has a marked effect upon psoriasis, without producing inflammation or staining as much as chrysarbin. Alkali baths increase its action.

Ten per cent. naphthol ointment has an increasing reputation in scabies; menthol, in 5 to 15 per cent., with a little alcohol and glycerin, is a most serviceable antipruritic, and takes away the pain of epilation; campho phenique, 1 drachm to the oz. of vaseline, often gives complete rest to an intolerable itching.—*Indiana Medical Journal*.

## A SIMPLE METHOD OF TREATING UMBILICAL HERNIA IN INFANTS.

DR. WALTER CHRISTIE, Physician to the Children's Dispensary, University Hospital, writes to the *Medical News*:

If the treatment of umbilical hernia in the earlier weeks of infant life has proved as troublesome and annoying to others as to the writer, this description of a simple and effective method of treatment will not be out of place.

Agnew and others use a button of cork covered with chamois skin, and held in place by a broad strap of porous or rubber adhesive plaster encircling the trunk. Elastic bands, pads fastened to the binder, hard rubber spring trusses, and various more complicated devices are also recommended. Most of these methods I have used, all with discomfort to the child and unsatisfactory results. Porous plaster invariably irritates the skin, as does rubber adhesive plaster, and their removal causes a paroxysm of crying when the consequent straining is most undesirable. All absorbent pads become malodorous from retained perspiration, and are constantly moist from the daily baths. Bands extending around the waist interfere with respiration, peristalsis, and the development of the abdominal and lumbar muscles. Elastic bands are by far the worst in this respect. Pads fastened to the binder are constantly slipping out of place. The same may be said of trusses, which have the additional disadvantage of hurting a child that is not handled carefully.

An apparatus for successful treatment should be non absorbent, non-irritating, and of such material that it will remain in place for at least a week, notwithstanding daily bathing. It should not interfere with peristalsis, respiration or development, and must be free from the possibility of

hurting a carelessly handled child. Such requisites are combined in the following device, which differs slightly, but in important particulars, from others.

It consists of a hard-rubber, slightly oval, plano-convex lens, with a greater diameter of 3 cm. and thickness of 6 or 7 mm.; on the plane surface are two small wire loops facing each other at a distance of 2 cm. This is attached to the center of an adhesive plaster strap, 2 cm. wide, and long enough to embrace three-fourths of the child's body, by thrusting the wire loop through the plaster and a small safety-pin through the loop. No plaster other than a reliable emplastr. resin. of the Pharmacopœia should be used. In using, the hernia is reduced by the pressure of the button, and the warmed plaster quickly applied while the child is quiet. This will retain its position for from one to three weeks, unless considerable soap is used in the bath. When removal is desired, a few moments' soaking with soap and water will loosen it unnoticed by the child. If redness of the skin is produced, the cause will be found in the adulteration of the plaster with turpentine or Burgundy pitch.

#### WHITE LEAD IN THE TREATMENT OF ERYSIPELAS.

(By E. STUVER, M.S., M.D., of Rawlins, W. T.)—During the last four or five years I have treated a number of cases of erysipelas with ordinary white lead ground in oil, thinned to a proper consistency with Japan dryer, and so prompt and efficient has been its action that I desire to call attention to its merits.

I have tried quite a number of the most highly lauded remedies, including the combination of sulphichthyolate of ammonium and lanolin, which is claimed by many to be a specific in this disease, but in my hands white lead paint has exerted a more favorable influence than anything else. It very promptly relieves the burning pain and feeling of tension which are so marked in severe cases; it limits the spread of the disease process, and forms an impermeable covering over the affected parts, thereby preventing the dissemination of diseased particles. If this disease, as is now generally admitted, be caused by pathogenic microorganisms, this power of the treatment to limit the spread of the disease germs should lead to its more general adoption.—*Medical News*.

#### THE INCUBATION PERIOD IN INFECTIOUS DISEASES.

DR. JAMES FINLAYSON (*Glasgow Medical Journal*, May, 1889), in preparing a code for the regulation of the school attendance of children exposed to or affected by infectious diseases, found that there was a decided diversity of opinion among authorities as to duration of the incubation period and as to the time of quarantine for

children that had been exposed. The incubation period in scarlet fever is given as low as 1 day and as high as 14 days, with an average duration of quarantine from 10 to 14 days; measles, from 3 to 17 days—quarantine 16 days; röteln, from 4 to 21 days—quarantine from 16 to 21 days; mumps, from 4 to 24 days—quarantine from 21 to 24 days; whooping-cough, from 4 to 14 days—quarantine from 16 to 21 days; chicken-pox, from 2 to 18 days—quarantine from 18 to 21 days; small-pox, 5 to 19 days—quarantine 16 to 18 days; diphtheria, 1 to 14 days—quarantine 10 to 12 days; enteric fever, 1 to 30 days—quarantine 28 days; typhus fever, 1 to 21 days—quarantine 21 to 28 days; erysipelas, 1 to 13 days—quarantine 10 days. As in the United States local ordinances involving this question require the physician to furnish a certificate to the child, the periods of quarantine above given may serve as precedents.—*New York Medical Journal*.

#### TO STERILIZE MILK.

It is not necessary (*Dietetic Gaz.*) to invest in a sterilizing apparatus, as any housekeeper can arrange one equally efficient for herself. All that is necessary is to have some bottles, capable of containing the milk to be used in a day; each large enough to contain what will be needed at one time. These bottles and their corks should be thoroughly cleansed by boiling in a solution of washing soda. The corks should be selected, and of the best variety. When the milk is brought to the house it should be placed in these bottles, which should be arranged on a wire frame in a pot of water, and boiled for fifteen minutes. They should then be corked securely and placed in the refrigerator with the ice *upon* them, not under them. In the country they may be lowered into the well. Milk thus treated will not only keep sweet and fresh, but almost any impurity it may originally contain will be rendered innocuous. The flavor of boiled milk is unpleasant to many persons; but this may be remedied by the addition of a little coffee or cocoa. At any rate one must not expect too much in this world, and for the sake of safety put up with the unpleasant taste, or learn to like it.—*The Canada Lancet*.

#### CASTOR OIL AS A MENSTRUUM FOR COCAINE.

DR. S. MITCHELL writes in the *New York Medical Record* of the happy results following the use of castor oil as a solvent for cocaine. A patient had been attacked with herpes zoster, the eye being much affected. Great pain was felt from the hard cicatrix resulting from the healing of a vesicle. Castor oil was applied as a lubricant, and the doctor then conceived the idea of adding cocaine. A 5 per cent. solution was used, by which the pain was relieved. Recovery was rapid.—*Druggists' Circular*.

## SOCIETY PROCEEDINGS.

## Medical Society of Virginia.

(Concluded from page 539.)

DR. I. S. STONE, of Lincoln, read a paper giving an account of

## SOME GYNECOLOGICAL WORK OF THE PAST YEAR

The author stated that his cases were treated in his private sanatorium, where they could have good surroundings, nursing, etc. Four cases of abdominal section for tumor of the peritoneum with cancer of transverse colon, salpingitis, chronic peritonitis following salpingitis, and one Battey's operation, were respectively reported. The specimens shown (three in number) were characteristic of the disease in question. Other cases of lacerated cervix and perineum were alluded to briefly but not separately reported. The author still advocates Emmet's operation for lacerated cervix, but says he does not so frequently perform it as before. One case of modified hysterorrhaphy was mentioned in which Alexander's operation was done on the left side and a partial hysterorrhaphy on the other. It was ascertained that many minor disorders, not surgical, were to be successfully treated by massage, electricity and over-feeding known as the Weir-Mitchell method. The author has had several years of experience in treating these cases, and justly claims that a very large percentum of cases come under this heading. Electricity was not spoken of at length, but enough was said to show some skepticism in regard to its value in all save in nerve complications.

DR. JOHN W. SCOTT, of Gordonsville, Va., was the reporter on

## PRACTICE OF MEDICINE.

After reviewing much of the germ theory as causative of a number of diseases, he concludes that we must look to local sanitary improvements rather than to quarantine alone for the prevention of epidemics, such as Asiatic cholera, yellow fever, etc. Gibier maintains that the bacillus of yellow fever closely resembles that of cholera. During the year ending May 1, 1889, Pasteur treated 1,673 persons bitten presumably by rabid dogs, and lost only three by hydrophobia after the conclusion of the treatment; six died during treatment, and four developed the disease a fortnight after leaving the institution. The microbe of typhoid fever is the bacillus of Eberth and Gaffky. It is of tenacious vitality, and may live for months in decomposing faecal matter, increasing in numbers at a temperature of 62.5° F. Drs. Kalb and Bartlett claim (*Brit. Med. Jour.*, Jan. 5, 1889) what is next to an abortive treatment of typhoid fever by mercurial inunction. This treatment must be commenced before the ninth or

tenth day. Cold baths are being again advocated. Ehrlich's diagnostic sign of enteric fever—reaction in the urine with one of the aniline derivatives—has been verified by Dr. Taylor (*Lancet*, May 4, 1889). Tuberculosis is a specific infectious disease, the constitutional manifestations of which are secondary to the bacilli, and due to toxic influences evolved during their increase of growth and number. The number of the bacilli in the sputa bears no relation to the progress of the disease. The dry sputa is chiefly concerned in the propagation of the disease. The disease can be transmitted only through the medium of Koch's bacillus. It is not in the ordinary sense hereditary. The presence of the bacillus in the sputa is of positive value, but not of negative value in diagnosis. A rational prophylaxis is practicable, and we must still look more to prevention than to cure of tuberculosis, as no non-injurious antiseptic has yet been brought forth successfully. The infectiousness of scarlet fever suddenly decreases about the sixth day and increases again about the twelfth, reaching its maximum by the sixteenth. The telluric origin of tetanus is gaining advocates. The disease may be produced by inoculation with earth which has recently been in contact with organic matter. The treatment of locomotor ataxia by suspension is approved, but with the injunction to be cautious in watching the effect on the patient during the operation of suspension itself. No case of Pott's paralysis ought to be regarded as desperate until after failure of suspension. Weil's disease is due to septic poisoning, and hence it is proposed to call it septic or infectious icterus. Dr. Scott's observations on the treatment of whooping cough by inhalations of the oil of eucalyptus, is beneficial in shortening the length and in ameliorating the severity of the paroxysms, and in prolonging the intervals between the spells. His method was to pour from one to two drachms of the oil on sponges, and suspend several of them during the day from convenient places in the room; at night, from the head of the bed, so as to let the oil be constantly inhaled. A number of abuses of hygienic rules were mentioned, in the hope of getting practitioners to properly instruct their patients with regard to them, such as the common errors in our schools, the aversion of wives to becoming mothers, etc.

DR. A. JACOB, of New York, read a paper on

## ENTERALGIA AND CHRONIC PERITONITIS.

Enteralgia is always an irritation of a branch or branches of the sympathetic nerve. Its cause lies in the nerve or the intestinal tissues or its contents. Hysteria, hypochondria, malaria, gout, poisons, etc., may start the disease; or the pain may be reflected from spinal, liver, genito-urinary or skin disease, sudden chilling of the skin being a frequent cause. The pathological changes are

congestion or inflammation, with their results. Acid food, certain drastics, hard scybalæ, fermenting foods, etc., are the common causes of enteralgia. The attacks are indefinite in length or suddenness. The temperature is rarely raised; the pulse is irregular; the skin becomes cold and clammy; sometimes dysuria, nausea, vomiting, constipation or diarrhœa occur. The tumidity of the abdomen changes its place under palpation, etc. Priapism and seminal discharges may occur with spastic rise of the testicles.

A common cause of enteralgia, often overlooked, is chronic peritonitis of secondary nature. New abdominal formations, peritoneal adhesions, swelled pelvic glands, etc., point to previous peritonitis. Floating kidney may start peritonitis, and thus become fixed in its dislocated position. Vertebral disease, psoas and iliac abscesses, hip-joint abscess, etc., may cause chronic peritonitis, oftentimes not recognized except post-mortem. Catarrhal "female diseases" are frequent causes, as are violent cohabitation, the puerperal state, etc. Biliary calculi, perinephritis, splenic and pancreatic diseases, infantile intussusception, a preceding attack of peritonitis, etc., are also causes. Simple intestinal catarrh grows speedily into enteritis. Peritonitis is likewise communicated to the muscular and mucous tissues, and thus extends the œdematous infiltration, paralysis, and hence constipation. Thus also diarrhœa, intestinal ulceration, without perforation, may cause local peritonitis. Diagnosis of chronic peritonitis is not always easy. Respiration need not be accelerated in pelvic peritonitis, perimetritis and pericystitis. Vomiting is sometimes wanting; diarrhœa is not infrequent, but constipation is the rule; the abdomen may be tumid, and the horizontal position is often uncomfortable. The seat of inflammation or adhesion may sometimes be told by placing the patient on his back, extend and then flex the extremities, and then use pressure, soft hard, sudden and gradual. Often, however, it is best to make deep pressure; if no pain, relieve the pressure suddenly; when localized pain may be felt. Change of position of the bowels may arouse pain; sharp pain, after full meal, may point to adhesions of the stomach; if pain occur three or four hours after eating, look for chronic colitis; if after quickened inspiration, then peri-hepatitis, etc. Variability of pain depends on degree of irritation or congestion. Extensive pelvic peritonitis may not give pain except when waked up by defecation, cohabitation, micturition, etc. In peri-cystitis, when urine is about half voided, and the bladder begins to contract, more efficiently, a localized pain above the pubes, increased by pressure, develops much resembling the spasmodic pain of vesical catarrh. Flatulence, etc., develop enteralgia in chronic peritonitis. Stenosis of the bowel, twisting, adhesions, etc., result, thus in-

terfering with the intestinal functions. In short, the sequelæ of chronic peritonitis are very various. The indications of treatment of enteralgia of chronic peritonitis are determined by its results and symptoms, such as intestinal sluggishness, adhesions, etc. Subacute and acute peritonitis require absolute rest, support for the knees, ice or hot applications according to circumstances, opiates, etc. Some are now recommending large doses of magnesia sulphate and turpentine enemata; but a treatment under which an occasional patient may escape death must not supersede one which has proven to be successful in most cases, and beneficial in all. Localized attacks, mainly in the right hypochondrium, demand local applications; a few leeches occasionally and morphia subcutaneously may be required. Old adhesions, etc., are not amenable to medicines. Great physical exertion, pressure on abdomen, etc., must be avoided. Keep bowels regular. Wear a snug bandage over the whole abdomen for years after the last complaint of pain. Generally this bandage, held down by a perineal band, gives immediate relief. Without the immobility given by it to the sore intestine, he does not expect a case of chronic peritonitis to do well.

DR. JOHN RIDLON, of New York, read a paper on

#### SOME PRACTICAL POINTS IN THE TREATMENT OF HIP DISEASE, WITH SPECIAL REFERENCE TO THE USE OF THOMAS' SPLINT.

Only the mechanical treatment of hip disease was considered, and that from the points of most interest to the general practitioner of medicine and surgery. The difficulties of obtaining, applying and satisfactorily caring for any of the forms of traction apparatus were pointed out. Plaster of Paris, when applied from ankle to axilla, was considered as a comfortable and satisfactory dressing, but not easy to apply to many cases. Traction in bed by the ordinary Buck's extension and weight and pulley was not to be used except as a temporary expedient. On the other hand, traction after the manner of Howard Marsh was very useful in those cases where traction was indicated, and rest in bed not contra-indicated. Thomas' splint would prove of great service to those who were satisfied to treat tubercular joint disease in any part of its course without traction, to those who were so circumstanced that they could not use traction in their walking cases, and to those who believe that immobilization, and not traction, is chiefly indicated in the management of these cases. The splint can be made by any blacksmith and harness maker, and should not cost more than \$2.50. Splints, patens and wrenches were shown, and their construction, application and management explained. It was urged that the splint should not be considered as essentially a walking splint, but that

it was of more service while the patient was still confined to the recumbent position. With it the patients are not necessarily confined to bed as is the case when Marsh's method is employed. When the involuntary muscular spasm has subsided, patients are allowed to go about on crutches and a high patten. When the disease is believed to be cured, the crutches and patten are dispensed with: after a few months the splint is shortened up so as to allow of motion at the knee, and thus worn for a few months longer.

DR. JOSEPH A. WHITE, of Richmond, Va., presented the

#### REPORT ON ADVANCES IN OPHTHALMOLOGY, OTOTOLOGY AND LARYNGOLOGY.

He stated that there had been no brilliant discovery and no new field of research opened up in this line of work, while much had been done in a quiet way to advance the diagnosis and treatment of these special diseases. In ophthalmology, the discussion on *iridectomy in cataract extraction* would fill volumes—the tendency of most writings being a return to the “simple extraction.” In the opinion of the reporter, both simple extraction and extraction with an iridectomy have their application, and a surgeon cannot confine himself to either. The after-treatment has also been modified, and some writers even go so far as to dispense with the commonest rules of conservative surgery, allowing the person operated on to walk about as usual, with the unprotected eye open and the other closed by a piece of plaster. The reporter thought prudence would suggest the same rest, quiet and surgical precautions against failure, as in other surgical procedures. In *detached retina*, Prof. Schoeler, of Berlin, has reported cures from injections of tincture of iodine, into the vitreous and sac, but as yet, no method of treatment has proved satisfactory. *Transplantation of the cornea* has been an experimental operation only, and with the exception of one case of Von Hiepel's, which was a partial success, all the attempts have proved failures, and even the so called successful ones. In defects of the ocular muscles, with or without refractive errors, headache, eyeache, etc., can be relieved by proper adjustment of the muscular action of the two eyes by prisms or anatomy. Dr. George Stevens, of New York, ascribes all kinds of reflex nervous disturbances, such as chorea, epilepsy, mental aberration, etc., as well as sick headache, neuralgia, etc., to the nerve irritation, resulting from imperfectly acting ocular muscles, and reports numerous cases of cures by the operative correction of the defect. Time will demonstrate the value of this view in regard to epilepsy, mental trouble, etc., but the reporter thinks there is no doubt of their correctness in regard to headache, eyeache, etc., as he has had extremely favorable results in such cases by following Dr.

Steven's method of tenotomy, resection of the recti muscles for their relief. Dr. Stevens in the past year has presented an instrument called a phorometer, which simplifies the determination of muscular defects, and is valuable in the saving of time and in producing greater accuracy. In his own experience the reporter finds that the modified tenotomy of a contracted tendon and resection of its antagonist gives better results in strabismus than the ordinary method of complete tenotomy, giving more perfect motion and a better chance for fine ocular vision.

In otology and laryngology, there is little to report, beyond noticing the facts that the dependency of aural diseases upon nasal troubles is becoming more generally recognized, and that the treatment of nasal diseases is becoming more strictly surgical—so-called catarrh being radically relieved only by surgical measures and not by local applications, which are only useful for cleansing and antiseptics.

#### PRIMARY IRITIS—ITS DIAGNOSIS AND TREATMENT.

was the title of a paper read by DR. J. HERBERT CLAIBORNE, JR., of New York. After an anatomical description of the iris and contiguous parts, he remarked that it was important to remember that in a condition of health, the edge of the pupil rested on the anterior surface of the lens in moderate dilatation. The diagnosis was to be made by the signs rather than the symptoms of the disease. The chief signs were pericorneal redness, steamy cornea, clouded aqueous, discolored iris, small pupil, irregular and puckered edges of the pupil, etc. Tenderness on pressure in the ciliary region was the symptom indicating a high stage of ciliary congestion, but not necessarily of cyclitis. Treatment was comprised under the great “therapeutic trilogy,” local depletion, dilatation of the pupil, and systemic treatment. Local depletion was best obtained by that leech that takes deepest hold, sucks the longest and draws most blood. Bleeding should be encouraged by hot applications to the bites. The position for the leeches was in the temporal fossa, in a horizontal line with the outer canthus of the eye, to drain the temporo-malar branches of the lachrymal arteries. He preferred to combine cocaine with mydriatics on account of the greater mydriatic power of such combination, and the analgesic effect of cocaine. He preferred duboisin (1 per cent.) combined with cocaine (6 per cent.). With regard to systemic medication, he uses blue ointment, salicylate of soda, iodide of potassium, the iodide combined with bichloride or the biniodide of mercury, antipyrin and Russian or Turkish baths, and quinine for its general tonic effect. He laid much stress on the value of salicylate of soda, especially in rheumatic iritis. It was also of great

value in the specific forms of the disease, as assisting the action of the other agents. There is no need of opium or morphia in iritis. If the pupil could be dilated, pain would cease; if it could not be antipyrin was a good substitute for morphia. Too much stress could not be laid on the importance of the early treatment of iritis with regard to preserving the sight. The responsibility of treatment rests on him who sees the case first.

DR. LEWIS G. PEDIGO, of Roanoke, reported on

#### ADVANCES IN NEUROLOGY AND PSYCHOLOGY.

He regarded the development of the suspension treatment of locomotor ataxia as the most important step of progress in neurology in the past twelve months, and devoted considerable time to the consideration of this subject. Other items of progress in neurology were reviewed; the problems of asylum management and general care and treatment of the insane received due attention. A brief allusion was made to Stephen Smith's project of a law for commitment and detention of the insane. The present status of various questions of medical jurisprudence was presented at length. The latter part of the paper was devoted to hypnotism and allied phenomena. This part of the paper was illustrated by actual experiments before the society on a subject who, the doctor claims, is one of the very best and, in some respects, most remarkable hypnotic subjects in the world. He succeeded, by his own modification of the Bernheim and Charcot methods, in throwing this subject into the hypnotic trance in about one-third the time required by Bernheim to hypnotize his very best subjects. *La Petite Hypnose* and *La Grand Hypnose* (in its three stages), as delineated by Charcot in *Salpêtrière*, were demonstrated in clear and rapid succession.

A paper by DR. E. M. MAGRUDER, of Charlottesville, Va., was presented, reporting two cases of

#### NEURECTOMY FOR FACIAL NEURALGIA, WITH RECOVERY.

His first case was a gentleman, aged 71, who had the persistent neuralgia for fourteen years that no medicine cured, although he had consulted eminent specialists. Seven drops of fluid extract of gelsemium every three hours gave greater relief than any other medicine, except morphia; but all medicines failing, the patient was chloroformed, and with strict antisepsis an incision was begun below the lower orbital margin, over the infra-orbital foramen straight downwards, parallel with the nose, towards the lip and ending on a level with the lower border of the alæ-nasi—about an inch incision. The fascia and fibres of the levator labii superioris were torn through with the handle of the scalpel and the nerve exposed at its exit, where it divided into its branches. Each branch, the palpebral, the

nasal and the labial, spreading into a fan shape as it neared its destination, was dissected out as far as it could be followed without mutilating the face too much. The main trunk was then seized with forceps at the foramen, drawn out as far as possible without breaking it, and cut off close to the bone, after which the various branches were divided at their farthest point of dissection. The wound was closed with fine silk sutures. There was at first considerable paralysis of the side of the face and loss of sensation, but these disappeared except from the right half of the upper lip, which is still without motion or sensation. There has been no recurrence of the neuralgia. The patient feels like a new man.

Case 2 was a lady, age 58, who has had facial neuralgia for ten years. At first it was confined to the left lower jaw, never passing the middle line of the chin, but afterwards extended to the left external ear, temple and side of the head above and behind the ear (auriculo-temporal) to the left side of the tongue (gustatory), and then to the left side of the floor of the mouth (mylo-hyoid). The diagnosis was neuralgia of the inferior dental nerve, with reflex and sympathetic phenomena exhibited by the auriculo-temporal, gustatory and mylo-hyoid nerves. As to treatment, teeth had been extracted, anaesthetics had been used, etc., and finally total neurectomy of the inferior dental nerve, including its branches, was done with cure. In the operation avoid injury of the facial artery and Steno's duct. Entering the scalpel just in front of the posterior border of the ramus, just below the parotid duct and lobe of the ear, a curvilinear incision was made downwards, half an inch in front of the inferior maxillary angle, then forwards a little above the lower border of the ramus, and upwards just behind, and avoiding the facial artery, stopping short of the line of Steno's duct above. The flap thus shaped was raised by shaving the masseter muscle from its attachment to the outer surface of the ramus and the bone laid bare. With a half inch trephine he cut out a button of the bone from the center of the outer plate of the ramus, exposing the nerve in its bony canal. Seizing the proximal end of the nerve with forceps, strong traction was made from the direction of its origin. It was then cut off with scissors close to the bone as it entered the circular cavity made by the trephine. Then, the wound being stuffed with moist antiseptic cotton and the hæmorrhage stopped with pressure, a second incision was made, an inch long, horizontal in direction, over the mental foramen (below the root of the second bicuspid tooth), beneath the depressor anguli oris, disclosing the mental nerve and its branches beneath the last named muscle. The nerve was grasped with forceps and pulled upon, but broke off at its point of exit. The branches were then dissected out and cut off as far as possible from

the foramen. Then returning to the first wound over the ramus, and chiselling away the wall of the dental canal, or one-eighth inch from the circular cavity in the ramus, so as to expose this end of the nerve, which had been divided by the distal side of the trephine, it was drawn out of the dental canal with forceps in its entire length from the ramus to the mental foramen. In all, 3<sup>3</sup>/<sub>8</sub> inches of nerve structure were removed. The wounds were closed and the patient was perfectly relieved without any return of neuralgia since. The paralysis of the left side of the face disappeared in about two weeks.

The lesson learned is: In all operations for facial neuralgia remove as much of the troublesome nerve and its branches as the anatomical formation of the parts will possibly allow without rendering the procedure too grave.

DR. C. R. CULLEN, of Waldo, Fla., read a paper on

#### RAILROAD INJURIES.

He reported eight cases of railroad accidents. He urged that doctors not engaged in the service of railroads insist upon the same compensation, when they are called upon for such service, that is received by doctors engaged in the railroad service.

DR. HUGH BLAIR, of Richmond, Va., read a paper on

#### DIAGNOSIS BY MEANS OF URINARY ANALYSIS.

Harley says the state of the urine is a key to the condition of the body. While some diseases may not affect the urine, morbid urine indicates disease. *Renal inadequacy* (notable absence of urea and other solids), due to want of the necessary nerve influence, is shown by the low specific gravity of the urine, other causes being excluded. In overworked nervous systems, excess of alkaline phosphates in the urine occurs. Probably the nervous system is fed with phosphorus to licithin. The best way of supplying phosphorus to licithin is to give hypophosphites. If indigestion and improper metabolism occurs, deleterious matters accumulate in the blood; if of nitrogenous character, the kidneys excrete them, if they are able. Destructive metamorphosis of albuminoids in the liver forms urea. Uric acid crystals, easily recognized by the microscope, appear in the urine in some functional hepatic disorders and lesions, causing gout, chronic nephritis, renal calculi, etc. If the crystals do not appear, excess of urates, acid urine, with high specific gravity, are present. *Lithuria* (uric acid in the blood) is a chronic condition of the overworked and over-anxious, is not so serious as gout, but is ever active in causing obscure and distressing symptoms. It points to chronic functional disturbance of the portal circulation, and is recognized by the high specific gravity of the urine, its acidity, excess of lithates and phosphates, and

often oxalate of lime crystals, and especially pigments in the urine. It gives a peculiar change in color to the urine during Pavy's copper test for sugar. *Diabetes* indicates grave systemic disease; but it should be differentiated from hydruria and polyuria. *Icteric urine* stains white cloth yellow, but its diagnostic value is not of practical use. In short, the value of urinalysis extends to every disease characterized by pathological urine, as the Bright's disease, pyelitis, cystitis, etc. Numerous urinalyses made by him for physicians had enabled the practitioner to determine their diagnoses and oftentimes save the lives of patients.

DR. A. F. KERR, of Williamsville, Va., reported a case of

#### EXTERNAL GLANDERS, OR FARCY IN MAN.

The rarity of the disease, especially in mountainous regions justified, he thought, a note or two about the case. Glanders is an infectious disease, principally of domesticated equine animals, and communicated to other animals, and to man by inoculation of the glanders bacillus. It originates in solipeds, although it has been known to originate in cloven footed animals. Having originated, infection occurs only for a short distance through the atmosphere, or the disease may be communicated through the ingestion of infected matter, or through the seminal secretions to the female in coitus, etc. In man, the chief source of infection is the horse—it being rarely communicated from man to man. The point of attack is usually an abrasion upon the skin or mucous membrane. The incubative period is from one to four days in inoculated cases. The wound becomes tense, swollen, painful, with a dark or yellowish erysipelatous redness, and the edges become puffy and everted. A sanious matter issues, and the surrounding lymphatics become swollen and red, and the glands become enlarged and tender. Constitutional disorder acts in a few days—languor, extreme weakness and prostration, with aching in the limbs and head, rigors alternating with fever, or a continued fever after the first violent chill: sometimes there is nausea and vomiting, and even diarrhoea. When not due to external inoculation, the febrile symptoms appear first, and then the other conditions, which have been noted first in the description of cases due to external inoculation. The phlegmonous swellings along the lymphatics become abscesses, and discharge small quantities of a thick slimy pus. The resulting sores become ulcerous with grayish base. Temperature rises perhaps to 104°.

His case was a young healthy man in 1886. He contracted glanders from treating a mare supposed to have "greased heel" or "scratches." He first noticed a painful swelling on the point of the second finger of the left hand, which had

been slightly cut with a pen knife. The swelling was yellowish, edges of wound everted and puffy, and discharged a thin sanious material; the surrounding lymphatics became enlarged and all the fulness of the history of glanders in man was complete. Treatment began with a brisk purge, followed by quinia and muriated tincture of iron, and an exclusive milk diet. The swellings on the forearm were freely laid open and cauterized with nitrate of silver, all diseased tissues removed, and the resulting sores packed with iodoform, over which was laid medicated jute. Subsequent washings were made with carbolyzed water. Recovery was prompt.

DR. W. W. PARKER, of Richmond, Va., read a paper on

#### A FEW ORIGINAL OBSERVATIONS ON BLOOD GRAVITATION IN HEALTH AND DISEASE.

of which the following is a synopsis:

1. The first wound ever inflicted upon the human body was probably upon one of the extremities, and the relief following the elevation of the wounded member was the first illustration of blood gravitation in disease.
2. A case reported of the wonderful curative power of elevating the leg at  $80^\circ$ , of a boy struck in the tibia by a base-ball.
3. A singular case of death from the application of a mustard-plaster to the ankle, being an exception to the rule, yet establishing it.
4. The gravitation of blood in the stomach made useful in preventing emesis in certain cases.
5. A remarkable case of acute inflammation of the neck of the bladder, in a woman, with retention of urine, at once removed by the forcible elevation of the hips of the patient. Other cases reported.
6. The avoidance of varicose veins of the legs in shop-keeping men and women by sleeping on a double inclined plane; and the importance of those predisposed to apoplexy, sleeping with the head well elevated.
7. The effect of the position of the body in phthisis, in liver and other congestions. A case of an infant with suffocating catarrh at once relieved by the elevation of the head and chest.
8. A beautiful illustration found especially in the herbivorous or grazing animal of nature's plan of counteracting the hurtful gravitation of blood to the brain.
9. A lesson suggested from these considerations and facts to those unwise doctors and deluded people, who think "a man cannot die till his time comes." That mechanical law in the body is as inflexible as the same law in the machine, and loss and ultimate destruction will come as certainly from neglect of these laws, to the one as to the other.

DR. A. C. PALMER, of Norfolk, Va., prepared a paper on

#### OUTLINE TESTS FOR MUSCULAR INSUFFICIENCIES OF THE EYE, WITH REPORT OF A CASE.

Leaving out of consideration cases of strabis-

mus, etc., he confined attention to the more minute forms of insufficiencies, known by the term *heterophoria*. In strabismus one eye soon accustoms itself to see the object looked at, while the other is idle as to effort at vision; but in heterophoria there is acute normal vision, in which every detail of an object is seen, but the external rectus of one or both eyes is just too weak to prevent the internus rectus muscle from turning the ball in, just past the normal axis. Eyes such as these have to swing a very little way to make the image seen with one eye a little to one side of that seen with the other, and the confusion resulting is all the worse from the very fact that each eye sees so clearly that neither image can be ignored. The patient has before him two similar images which are continually receding from and blending with one another; but he will involuntarily overcome this blurring of outlines if he can possibly spur up the externus muscle to pull the eye out to its proper place. Just these insufficiencies or strains produce more mischief than true strabismus. Heterophoria is subdivided into esophoria (eyes tend to turn in too far), exophoria (tend to turn out too far), and hyperphoria (where one eye swings on a higher level than its fellow). Prisms deflect an image towards their apices or their edges. The relative strength of each of the four recti muscles, in their normal conditions, are first presumed to be ascertained. Thus the externi should diverge the eyes sufficiently to make the image single when prisms of  $8^\circ$  are placed before them with their bases in. The interni, after a little trying, should converge sufficiently to single images when prisms of  $50^\circ$  are placed before them, bases out. If a patient with neurasthenia presents, place him in an erect position and direct his vision on a lighted candle, 20 feet off; then cover each eye alternately and notice whether the light moves up or down, or to the right or left. This paralax test, introduced by Dr. Alexander Duane, of New York City, often establishes at once the form of insufficiency; but should it not do so, then use the prism tests, which the paper describes in detail. Dr. Palmer then explained the application of glasses to overcome each of the insufficiencies.

DR. D. MAYER, of Charleston, W. Va., read a paper on the

#### USE AND ABUSE OF OBSTETRIC FORCEPS.

He showed that when the forceps are properly used they are not damaging; that harm may come when used too late; that the time has arrived in obstetric advances when the practitioner will be compelled to use them, because intelligent women demand their application to shorten their period of suffering.

DR. L. B. ANDERSON, of Norfolk, Va., presented the *Report on Hygiene and Public Health*, in which he classed the etiological factors into

(1) those which are known, (2) those which are purely hypothetical and chimerical, such as malaria, vegetable parasites, bacteria, etc., (3) those that are partly demonstrable and partly hypothetical, namely ptomaines and leucomaines, from which sanitary laws are deduced.

DR. J. G. WILTSHIRE, of Baltimore, Md., read a paper on *Anæsthetics*, but retained his manuscript for some revisions.

## DOMESTIC CORRESPONDENCE.

### LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

*Annual Meeting of the New York State Medical Association—The President's Address on Tubal Pregnancy—Laying the Corner Stone of the New Building for the Academy of Medicine.*

The sixth annual meeting of the New York State Medical Association, which was held at the Hotel Brunswick, during the last week of September, was, like all its predecessors, successful and interesting. The well arranged programme previously published was in the main faithfully carried out, and, as in former years, the chief features of interest were the set discussions on topics of scientific and practical value. This year there were three of these discussions, the first being on "Tubal Pregnancy," and opened by the President of the Association, Dr. Wm. T. Lusk; the second on "The Treatment of Hernia," and opened by Dr. Joseph D. Bryant; and the third on "The New Hypnotics: sulfonal, amyl hydrate, hydrobromate of hyoscin, hypnone, paraldehyde and urethran," and opened by Dr. Wm. H. Flint.

Among the most noteworthy separate papers were the Address in Medicine, on "The Bacteriological Test of Drinking-water," by Dr. Edward K. Dunham, which was a contribution of the highest scientific merit, and a paper by Dr. H. D. Didama, of Syracuse, entitled "A Few Fads," which was extremely full of the wit and dry humor so characteristic of its accomplished and genial author. A case of exceptional interest was also presented by Dr. Lewis Hall Sayre; this being one in which, for the first time on record, a patient has been enabled to wear an artificial limb after amputation at the hip-joint. The operation was performed (by Dr. Reginald Sayre) for bone disease (mollities ossium), in such a way that flaps were left with a sufficient amount of the muscles of the thigh to secure a certain amount of "grip" for the artificial leg; and there can be little doubt that the case inaugurates a new era in hip-joint amputations.

In the limits of this correspondence it is manifestly impossible to give even a satisfactory outline of the work accomplished at the three days'

session of the Association, and the remaining space at disposal for this subject will therefore be devoted to a brief consideration of the able and brilliant address of the President on "Tubal Pregnancy;" which, however, can afford but a very inadequate idea of its exhaustive character.

Dr. Lusk first reported two cases of tubal pregnancy of his own in which laparotomy was performed after rupture. In the first complete recovery followed and since the operation the patient has enjoyed better health than at any time previous in her life. In the second case the patient was affected with Bright's disease, and died from this cause on the eighth day after the operation. These two cases, he said, illustrated the ordinary history of tubal pregnancy. In both, without antecedent symptoms at an early period of gestation rupture with hæmorrhage took place; in the one instance the blood primarily making its way between the folds of the broad ligament, in the other passing suddenly, without check, directly into the peritoneal cavity. They were simply additions to the long list already furnished by Mr. Lawson Tait, upon which he had based his scheme of ectopic gestation. In Mr. Tait's belief all cases of extra-uterine pregnancy were *ab initio* of tubal origin. He denied the possibility of a primary abdominal pregnancy; while the ovarian form he regarded as possible, but not proven.

There was no question, Dr. Lusk said, as to the utility of Mr. Tait's scheme. It was based upon his exceptional personal experience and had received substantial support from the observations of others. It had stimulated active inquiry and given proper direction to pathological study; but the subject was still too new to make it possible for any scheme to be regarded as a finality. The most interesting outcome of Mr. Tait's work had been the change of view as regards the existence of primary abdominal pregnancy, and there was at present a very general agreement that the reported cases are at least open to grave suspicion.

In regard to the etiology of tubal pregnancy, Mr. Tait was unquestionably right in insisting upon the importance of the various forms of salpingitis. Owing to the associated loss of epithelium, the dilatation and other changes in the tube walls, the two active forces which propel the ovum through the tube, viz.: the ciliated movements and peristalsis, were weakened or destroyed, while free ingress was afforded to the spermatozoa. Or, again, the passage of the ovum might be interfered with by the secondary results of catarrhal inflammation, such as the production of mucous polypi, of adhesions, or of sac-like dilatations. Formerly great stress was laid upon the etiological importance of flexions and constrictions resulting from old peritoneal adhesions and inflammatory bands; but, curiously enough, in recent laparotomies for tubal rupture this cause had not played an important part. Recent observations

had also shown that there is a tendency of tubal pregnancy to recur.

The burning question at this moment connected with tubal pregnancy was that of early diagnosis. Dr. H. J. Hanks had recently stated his belief that a diagnosis can be made in 95 per cent. of the cases we are called upon to attend. Mr. Tait, on the other hand, thought "he might be excused for maintaining a somewhat skeptical attitude concerning the correctness of diagnosis of those gentlemen who speak of making a certain diagnosis before the period of rupture." In the main, Dr. Lusk said, our dependence must be upon local symptoms and local changes. The former consisted of the suspension of the menses, often followed, after a brief period, by bloody discharge, of paroxysmal pains, and of the discharge of the decidua. But the latter was by no means of constant occurrence, while paroxysmal pains were frequent in other forms of tubal disease, and menstrual disturbances were common phenomena in uterine derangements. As a matter of fact, the occasion for diagnosis must be very exceptional in the large class in which rupture occurs primarily within the peritoneal cavity. In the intraligamentous form the case was somewhat different. Here the swelling to the side of the uterus was easily reached through the vagina, and he believed in such cases that the chances of error were slight. He did not understand Mr. Tait to deny the possibilities of a diagnosis under such conditions. He differed only in regarding all intraligamentous cases as secondary to tubal rupture. Not much dependence was to be placed upon uterine changes in the early months; but after the third month it was not ordinarily difficult to determine the existence of the pregnant state. The distinction of physical signs between the tubal, the ovarian and the secondary abdominal form was scarcely practicable so long as trained anatomists failed to agree concerning them when the abdomen has been opened and the organs exposed to view.

A review of the subject of diagnosis made it apparent that many cases of ectopic gestation present no symptoms previous to rupture. In another class the existence of a suspicious tumor with few or none of the corroborative signs should lead to a waiting policy, or, when the symptoms were of a threatening character, to an explorative laparotomy. Upon the fact that in favorable cases certainty of diagnosis is attainable in the early stages of ectopic pregnancy rested the entire argument as to the validity of the treatment by means of electricity. The only argument against this treatment, except that the results reported carried with them the evidences of ignorance and folly, was that it is likely to cause rupture and that the retained ovum is liable to excite suppuration. But these eventualities were so rare that they might be left in case of need to a subsequent

laparotomy. It should be understood that this means of treatment was only available in the first three months, and that no one in this country, as was commonly assumed by foreign critics, advocates electro-puncture.

The argument in favor of the early use of galvanism did not in the slightest degree impair the value of laparotomy, which must always remain our most important therapeutical resource. Laparotomy not only possessed the advantage of being the one measure for the treatment of cases where, as in rupture, death is the common alternative, but it enriched our resources in cases of impending danger. Unlike the employment of galvanism, it presupposed the equipment necessary for laparotomy and the skill that comes from experience. It possessed this advantage: it leaves nothing to chance. All the possibilities are under the control of human intelligence; and, except for the question of ethics, it was available both before and after rupture. The late results with this procedure left little reason to doubt that when the anatomical conditions come to be properly realized human invention will find means to control the dangers of the so-called primary operation for extra-uterine pregnancy, and it too will find its place in the domain of legitimate surgery.

The corner-stone of the new building of the New York Academy of Medicine was laid in the presence of a large assemblage of physicians and distinguished men of other professions by the President of the Academy, Dr. Alfred L. Loomis, on the afternoon of October 2. On this occasion the invocation was by Bishop Potter and the principal address by Dr. A. Jacobi, ex-President of the Academy. The feature of chief interest, however, was an address by ex-President Grover Cleveland, who followed Dr. Jacobi, and this was delivered with that clearness, dignity and grace so characteristic of his public speeches. In the course of it he said: "To the members of this organization the corner-stone which we now lay is an honor, for it is a monument which marks an important advance in the attainment of the purpose of the Academy as declared in its constitution, 'the promotion of the science and art of medicine.' In these extensive foundations is also found proof of the progressive ideas of these earnest men and their constantly enlarging estimate of what is necessary to meet the purposes to which their energy is directed. . . . I am sure that you are not inclined to ignore the aid you have received in the project you have undertaken from the laymen among your Fellows. Nor can you forget that underlying all that you have done and all that you have received are our free American institutions, which encourage and give scope to every worthy effort and which offer fitting rewards for intelligent and well-directed labor in every condition of life. I hope that when we shall celebrate here the discovery of our country we

may point out on this spot, in your completed building, a splendid monument of the progress of our medical education, a monument which shall not only prove to the stranger that our physicians are proud of their profession, but one which shall also be a reminder that those who govern within its walls to not forget in their devotion to the science and art of medicine the other duties of citizenship."

It did not perhaps occur to the illustrious speaker how much more is done for the fostering of scientific investigation by some of the "effete monarchies of Europe" than by the great and glorious Government resulting from our free American institutions.

P. B. P.

### The Rush Monument Fund.

The attention of the secretaries of county medical societies throughout the United States is called to the resolution adopted at the meeting of the American Medical Association at Newport, "that one member of each county medical society in the Union be appointed to solicit funds for the *Rush Monument*," and they are requested, at the next meeting of their several societies, to ask that such a member be designated for this purpose, and to send his name and address either to the undersigned, or to Medical Director Albert L. Gihon, U. S. N., Chairman of the Rush Monument Committee, U. S. Naval Hospital, Brooklyn, N. Y.

All subscriptions, however, should be remitted directly to the Treasurer of the Rush Monument Committee, Dr. DeWitt C. Patterson, 919 T street, N.W., Washington, D. C.

WILLIAM B. ATKINSON,  
Permanent Secretary A. M. A.

1400 Pine street, Philadelphia, Pa.

### Unusual Length of Funis.

*To the Editor:*—I wish to report a case which, although by no means unique, is, nevertheless, not without interest. I recently attended a young woman, 22 years of age, in her first confinement. She was of slight figure and weighed less than 100 pounds. The child (which was found to weigh 9½ pounds) was born in a condition of *asphyxia livida*, a condition produced by reason of a coiling of the funis around the neck. There were five of these coils, drawn very tight, notwithstanding which circumstance there was an abundance of slack left. The child was resuscitated without much difficulty, and in half an hour the placenta was delivered by Crede's method. The latter was of unusual size, being far larger than any other placenta I ever saw, although, as usual in such cases, it was by no

means proportionately thick. When expelled it was rolled up like a scroll. Following the third stage of labor there was a very considerable flow of blood, although the uterus contracted fairly well. This, however, soon stopped after the removal of a large quantity of clots from the vagina and cervical canal. There was a very apparent relation between the area of the placental insertion and the amount of blood lost. The cord measured 48 inches in length and was not especially attenuated. This length, although very unusual, has no doubt often been surpassed. Schneider recorded a funis 120 inches in length which made six turns around the child's neck; Bandelocque reported an instance in which a cord of 59 inches had seven coils; Mme. Waldwogel mentions a case in which there were eight coils.

Yours truly,

JUNIUS C. HOAG, M.D.

Chicago, October 9, 1889.

### BOOK REVIEWS.

CATALOGUE OF SHARP & SMITH, IMPORTERS, MANUFACTURERS, WHOLESALE AND RETAIL DEALERS IN SURGICAL INSTRUMENTS AND DEFORMITY APPARATUS. Chicago, 1889; pp. 973.

This is a voluminous and excellent catalogue. It is very complete and well illustrated. Its arrangement is convenient. It is to be commended among trade publications.

THE PHYSICIAN'S LEISURE LIBRARY, SERIES IV. SYPHILIS OF THE NERVOUS SYSTEM, by H. C. WOOD, M.D., LL.D.; pp. 135. 1889. Detroit: George S. Davis.

The medical public is always glad to hear from one of its most honored exponents in this country, Dr. H. C. Wood, and if, therefore, an interest be awakened by the announcement of a new brochure bearing the above title, we can assure our readers that they will find no cause for disappointment in a perusal of the particular volume in question. There are few physicians who are in a position to speak more authoritatively upon this subject than Dr. Wood, who has reached the conclusions herein set forth from a study of 2,000 cases of nervous disorders associated with syphilis. Among the many points of interest made by the author is this one: That there is a syphilitic insanity which exists without obvious meningeal disease, and is capable of being cured by antisyphilitic treatment, in support of which view a table of illustrative cases is given with regard to the method of antisyphilitic treatment by the hypodermic injection of the insoluble salts of mercury, a method which has been greatly praised by some European physicians. The

author finds that the dangers of local inflammation are so great as to overbalance any special advantage which might thereby be gained. His first experience in its use resulted so unfortunately as to discourage its further employment.

## MISCELLANY.

THE MCLEAN COUNTY (ILL.) MEDICAL SOCIETY met in the regular session at the office of Dr. C. J. Corley, October 7, at 3 P.M. There were present Drs. H. Parkhurst, M. Wilson, Wm. Hill, N. F. Jordan, F. J. Parkhurst, C. J. Corley, S. T. Anderson, C. C. Sater, A. L. Chapman, F. C. Vandervoort and M. D. Hull. Dr. C. E. Ballard, of Saybrook, was elected to membership. Dr. Wm. Hill was elected to fill the vacancy on the Board of Censors. Dr. F. J. Parkhurst's essay on "Electricity as a Therapeutical Agency" was very interesting, his explanation of the different kinds of instruments used showed him to be a man well versed in scientific principles. A vote of thanks was tendered the doctor for the excellence of his paper. Dr. D. A. White's essay on "Scarlatina" was attentively listened to by all present. Drs. M. D. Hull and William Hill were appointed essayists for the December meeting. The Society adjourned to meet the first Monday in November.

## LETTERS RECEIVED.

Dr. H. Bart Ellis, Los Angeles, Cal.; Dr. C. W. Irion, Rocky Mount, La.; The Subscription News Co., Chicago; Dr. F. E. McKim, Marietta, O.; Dr. Wm. Pepper, Philadelphia; Dr. C. N. ## ORIGINAL ARTICLES.

### THE INDUCTION OF PREMATURE LABOR IN THE BRIGHT'S DISEASE OF PREGNANCY.

*Read in the Section of Practice of Medicine, Materia Medica and Physiology, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY JAMES TYSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF  
PENNSYLVANIA.

In reviewing my experience with Bright's disease associated with pregnancy, either as a consequence or an accidental complication, I have been led to believe it possible to formulate more precisely than has been done, the conditions under which premature labor may be induced with a view to averting the tragic termination so often met, premising also that I believe that certain lives now lost might be saved.

I would recommend the induction of premature labor with a view to saving the life of the patient, first, in cases of Bright's disease complicating pregnancy where in a previous pregnancy there has been puerperal nephritis with grave complications. Such are illustrated by the following:

Mrs. N. P. A., when pregnant at 25 years of age with her second child, first noted swelling of her feet when six months advanced. Thence dropsy spread over the entire body, including the face. During this time there were albuminuria and amaurotic symptoms. At eight months she miscarried with a dead fetus. For two or three days after this she seemed to be doing well, when there occurred a sudden aggravation of symptoms, inexplicably ascribed by the physician in attendance to hydro-pericardium. While apparently at the worst she lay back, in a short time fell asleep and slept ten hours almost continuously. After this she began to improve, and the decided symptoms of dimness of vision which had preceded her labor and had continued, disappeared suddenly. Four hours later, however, there occurred complete paralysis of the right side, with entire loss of speech, but not of consciousness. There was also some mental hebetude. She did not speak a word for three weeks, after which she began slowly to improve in speech, and gradually to acquire the power of motion. When I was first consulted, June 26,

1885, a year had elapsed since her miscarriage. She could say almost anything by speaking slowly and she could walk half a mile without apparently dragging her foot, but there did seem to be some stiffness at the ankle. She could not open the fingers of her hand, but could close them; she could move her arm at the shoulder better than at the elbow. This history I had from her husband. I did not see the patient then or at any time. A specimen of urine, brought to me at this time, I found strictly normal.

On May 20, 1888, just about three years after I was consulted, and four years after the conception alluded to, Mrs. A. again conceived. She had the usual signs of pregnancy, and up to November 20 inclusive, being at the beginning of the seventh month, she was free from any signs of nephritis, as shown by examinations of the urine on three separate occasions.

On the 11th of December, three weeks later, her husband reported that for some time, probably a month, there had been slight swelling of the legs, and that this had rather suddenly increased on December 1, when it was noted above the shoe tops. There was also slight puffiness in the hands, while the swelling was evidently greater in the hand of the paralyzed (right) side and the leg of the sound side. A specimen of urine brought at this date contained one-fifth its bulk of albumen, some vaginal epithelium, but no tube casts. On December 17 the husband reported a decided reduction in the twenty-four hours' urine, while I found it containing one-half its bulk of albumen and numerous *hyaline tube casts*. The patient's general condition was reported about the same. A week later, December 24, at the beginning of the eighth month, while apparently quite as well as usual, Mrs. A. fell into a convulsion about 11 A.M. from which she never recovered, dying the same evening.

In this case I had advised putting off interference until some more actively dangerous symptoms presented themselves, an advice which, in the light of subsequent events, I believe to have been bad. The dangerous symptom was the lightning's flash which allowed no time for intervention. On the other hand, I think there is every reason to believe that if premature labor had been induced soon after the appearance of decided al-

buminuria the patient's life would have been saved. Under the same circumstances I should strongly advise premature labor. Observe, however, that it is in view of the fact that we had in the previous pregnancy of the same patient Bright's disease with symptoms of great gravity, and this fact I believe to be the turning-point in cases of this category.

Second. I would advise the induction of premature labor with a view to saving the life of the patient in all primiparæ in whom there is Bright's disease previous to pregnancy. So many cases of this kind have come under my notice in which death terminated a terrific scene at the first confinement that I have grown to regard the girl thus afflicted as walking to her sacrifice as she walks to the altar, and if the opportunity presents I discourage marriage in the strongest terms. Should it happen, however, that a girl thus afflicted does marry, she should never be allowed to go to term, but premature labor should be induced as soon as the fœtus is viable. I have often wondered, if the proper examination of the urine were made in every case before marriage, how many of those in whom a fatal puerperal nephritis developed would have shown albuminuria. I am inclined to believe the proportion would be surprisingly large.

Third. There remain only to be considered those cases of puerperal nephritis not included in the first and second categories, viz.: those in which we have not the knowledge gained by experience with a previous occurrence of the disease in the same patient, and those which are not primiparæ having Bright's disease previous to marriage. They include, therefore, acquired puerperal nephritis in primiparæ, acquired puerperal nephritis in multiparæ present for the first time, and acquired puerperal nephritis in multiparæ where a previous labor has been accomplished without serious results. These are in fact the cases in which it is most difficult to decide treatment, because the data determining action in the other cases are wanting. It is evident, therefore, that each case must be decided on its own merits. One fact of importance in the natural history of these cases must be emphasized as having an important bearing on the treatment, and that is that a large number of them terminate by miscarriage, and when they do so the patient is generally saved. I did not realize until recently how common this accident is, and was surprised in looking into the cases with which I have had to do to see how large a number miscarried. These cases, too, terminated favorably in every instance for the mother, but more rarely for the child. The following is a good illustration of this class: A young woman of 22, a patient in the Philadelphia Hospital, somewhat past the seventh month of pregnancy, developed uræmic symptoms. She had an albuminuria ranging from one-twentieth to one-tenth bulk. At times there were no casts in

the urine, at others were found casts of several kinds, including granular, hyaline and epithelial, and even waxy and pus casts. There was undoubtedly puerperal nephritis. A consultation decided on the induction of premature labor, but pending some further study of the case by myself she miscarried, certainly when not more than seven and one-half months advanced. The child died in four days, but the woman did well. This frequency of miscarriage in puerperal nephritis I find generally attested by others.

Another very similar case was seen with Dr. Koser, of Shippensburg, Pa., and Dr. Oliver, of Philadelphia. Mrs. F., æt. 26, married about eighteen months, miscarried with her first child at about three months, and when I saw her was six months pregnant with her second child, having conceived about the 26th of April, 1888. After the first miscarriage she had a little dimness of vision in her left eye, but apparently recovered completely. In July, 1888, she returned from a summer trip with severe neuralgia and more than the usual amount of morning sickness. Early in October a trace of albumen was found in her urine. Visual symptoms presenting, she came to Philadelphia to consult Dr. Oliver, who found *retinitis albuminurica* and sent her to me. There were no other symptoms of Bright's disease, except that she had to rise once at night to pass water, although this had been her habit as far back as she could remember. Her urine contained one-twentieth its bulk of albumen, but no casts. I gave the opinion that she had puerperal nephritis, but recommended that her bowels and kidneys be kept acting, but that no more active treatment be pursued until some more urgent symptoms supervened. She returned to her home and when next I heard from her she had miscarried, November 7, when apparently six and one-half months advanced. She made a good recovery.

These two cases go to show not only the tendency to miscarriage, but also the less dangerous nature of these cases.

That this termination is not invariable and that a case may progress to full term without accident is shown by the following case, seen in consultation with Dr. Parish, of Philadelphia:

Mrs. J., always delicate, never weighed more than 100 lbs.; had diphtheria at 19, but there is no evidence to show she had nephritis before she married. Four months, however, after conception, Dr. Parish found albuminuria. On February 19 I was consulted, when the albumen equaled one-half bulk, and there were hyaline, pale granular, and epithelial casts. There was also some œdema of the face and legs. It was decided to put her to bed, to eliminate gently by saline aperients and await more serious symptoms. A few days later, however, it being supposed she was nearly at term, it was decided to induce premature labor on February 27. On going to the house

for the purpose, Dr. Parish thought he recognized some symptoms of labor, and the next morning he found labor progressing. She was confined on the morning of March 2 without other complication than extreme exhaustion, from which she was, however, desperately ill, but ultimately recovered. The child also lived. Whence too, we may infer that it is not always necessary to induce miscarriage in order to save the patient; but note that these cases belong to neither of the two divisions of the first category.

Reverting to the third category of cases, it is plain that no definite course can be laid down. Each case must be decided on its own merits. In general, however, it may be said that the super-vention of uræmic symptoms demands immediate interference, but, in consequence of the variety in these and their occasional simulation by symptoms due to other causes, great care must be observed lest an error in diagnosis be made. So also a marked degree of other symptoms of Bright's disease, such as interfere with important and necessary functions, may justify interference. As a rule, too, the same symptoms are more serious in robust women than in the delicate and less hardy. It is scarcely necessary to say also that Bright's disease acquired in the first pregnancy is a much more serious complication than in a later one, and although less serious than a Bright's disease previous to marriage on which a pregnancy has supervened, labor is rarely terminated without grave symptoms, while the patient often pays the penalty of her life. Under these circumstances, therefore, when the symptoms are of a positive or dangerous character, I should also favor the induction of premature labor.

DR. VAUGHAN remarked that certain women always have uræmic symptoms during pregnancy. We do not really know of what these symptoms are due, since it has been found that the urea is not a very poisonous agent. He agreed with the author that premature labor should be induced early in these cases, because if the condition has manifested itself once or twice it will surely return, and sometimes very quickly. The speaker cited a case in illustration. The patient had been pregnant several times and had convulsions in each instance. During the last pregnancy, twenty-four hours after an examination showed normal urine, albumen was found and she passed into uræmic coma. According to the speaker's opinion it is the wisest plan not to allow the women to go to full term. In primiparæ, however, we are not justified in acting so hastily. We know that the poisonous elements are formed from the proteids in the food and tissues. The speaker thought we could accomplish much with diet. Abstain from proteid food and keep up free elimination. He had in this way carried his cases safely through the dangerous period.

DR. ATKINSON thought the question should be confined to the consideration of the conditions which justify the induction of premature labor. It is just in primiparæ that we fear puerperal convulsions. According to his experience the contracted kidney is the most prolific cause of this trouble. He has had two or three cases that resulted most happily. He did not believe in one moment's delay after the mildest symptoms are manifested. Those suffering with other than the contracted kidney get along better.

DR. CHAMBERLAIN thought it best to carry the case on until the child has become viable. We often find that a miscarriage will occur while symptoms of albuminuria are disappearing.

DR. CARPENTER had been fortunate to see the larger number of such cases recover. He coincides that the contracted kidney was the most frequent cause of puerperal convulsions. If the cases be treated vigorously and promptly, we are often able to carry mother and child safely through the dangerous period.

DR. WILSON thought that the prophylactic measures proposed by Dr. Tyson would not likely be carried out. But in handling pregnant women the accoucheur may lay down certain rules, such as examining the urine every month, and thus be enabled to early recognize and treat the affection.

## NOTES ON HOANG-NAN IN DISEASES OF THE SKIN.

*Read before the Section on Dermatology, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY JOHN V. SHOEMAKER, A.M., M.D.,

OF PHILADELPHIA, PA.

Hoang-nan is the native name of a plant which has been classified as *strychnos Gauthieriana*. It is a climber and belongs to the natural order *Loganiaceæ*. It rises unsupported upon a slender stem to a considerable height, when it winds around the branches of tall trees. Its stem is gray and its leaves dark green. On account of a resemblance to the convolvuli it is also known as tropical bindweed. Its specific title is in honor of the Roman Catholic missionary, M. Gauthier, by whom, in 1874, it was introduced to the notice of French physicians. Its habitat is the mountainous districts of Laos, Anam, Tonquin and Cambodia. It has been enthusiastically heralded as a remarkable remedy in leprosy, rabies, snake bite and fever. I have been engaged for some years in a study of its therapeutic virtues, and regret to say that my experience does not enable me to endorse the extravagant eulogies of some of its advocates. More recently, also, laudatory articles have appeared in the *British Medical Journal* and other periodicals, both domestic and foreign, with the tenor of which I am unable to concur. Nevertheless, the article has a wide sphere

of applicability and is a valuable addition to our resources.

Belonging to the genus *strychnos* its bark, which is the portion used, contains the alkaloids strychnine and brucine, the latter in larger proportion. Allied thus botanically and chemically, its medicinal action bears a close resemblance to that of *strychnos nux vomica*. In small doses it quickens and invigorates the heart, accelerates and deepens the respiration, stimulates secretion and, consequently, promotes the nutrition of the organism. Experiments upon frogs, rabbits and dogs show that in moderately large doses it produces clonic, succeeded by tonic convulsions. In excessive doses it causes a rapid and considerable decline of arterial pressure, powerful tetanic spasms, death occurring from respiratory failure and probably due to exhaustion of the respiratory centre. The heart continues to act, in warm-blooded animals, for a few minutes after respiration has entirely ceased.

In its home it is used in pill form made up with realgar and alum. In this country a fluid extract and a tincture have been prepared. I have usually depended upon the fluid extract, giving it in doses of from 5 to 30 drops in water three times a day. It is best given just before meals. It is promptly absorbed and is eliminated principally by the kidneys and the bowels, though I believe that the skin also assists in its removal. It increases intestinal secretion and peristalsis and has, therefore, a laxative effect. As it sharpens the appetite and improves digestion it beneficially influences nutritive processes. From among the diverse pathological states in which it may be advantageously prescribed I have selected for consideration before this Section those which concern the dermatologist.

I have adverted to its influence upon the glands of the skin. This consists in a stimulant, corroborant or alterative action upon the cutaneous glandular systems, both perspiratory and sebaceous, but more particularly the latter. By accelerating the circulation and by communicating increased tone to the muscular fibres surrounding the gland ducts it encourages healthy secretion. Accordingly, I have observed that it exerts a corrective power upon both the quantity and the quality of the secretions, increasing those fluids when they are repressed and checking them when excessive. This property which *hoang-nan* possesses renders it a valuable agent in the treatment of disordered secretion. I have witnessed marked improvement follow its use in *seborrhoea*. As this malady interferes with the growth of the hair, any measure which cuts short its progress obviates a tendency to baldness. In *alopecia*, likewise, *hoang-nan* has proved very serviceable in my hands. In *hyperidrosis* it is no less beneficial for the same reasons. In *anidrosis* it will often restore the functions of the glands, and in *bromidrosis* will efficiently assist

the action of the local measures employed. Some obscure defect of nervous energy often lies at the foundation of these functional troubles. A substance, therefore, like *hoang-nan*, which combines tonic and alterative properties, is eminently calculated to prove of service. In *acne* its corrective influence is often able to effect very happy changes in the morbid process. It softens the sebaceous plug and favors its discharge and, in consequence, the subsidence of the resulting folliculitis or perifolliculitis. In *sycosis*, also, which so often depends upon obvious nutritive failures, this drug has manifested an excellent remedial quality. I have seen marked improvement take place in *eczema pustulosum* from the administration of *hoang-nan*. As this form of the disease is very prone to occur in ill-nourished subjects, a remedy which promotes constructive metamorphosis is especially indicated. Amelioration was particularly observed in cases attacking parts of the body abundantly supplied with sebaceous glands. The inflammatory process has been abridged in *furunculus* by the timely use of *hoang-nan*. I have observed good results likewise from its use in *carbunculus*. Individual cases of *purpura* differ so widely in etiology that a wise selection of curative agents is extremely desirable. I have met with success in some cases of this affection treated by means of *hoang-nan* to the exclusion of every other remedy, so that the improvement could be ascribed to it alone, aided only by proper dietetic and hygienic measures. I have made trial of it in *erysipelas*, but am unable to report any decided results. It did not appear to be as effective as iron and quinine or *pilocarpin*.

Leprosy is a disease which, in this part of the world, the physician is not often called upon to treat. In one case, however, which was under my care, I kept the patient upon *hoang-nan* continuously for three months. My experience failed to corroborate the very glowing statements which have been made as to its value in this affection. Some gain in the constitutional condition may have resulted, but I cannot say that I was able to satisfy myself that the slightest effect was produced upon the local lesions.

Speaking broadly, all conditions of the skin—and they are many—which are either produced or are attended by digestive failure, an exhausted state of the nervo-muscular system or the imperfect function of glandular organs, may be benefited by the administration of *hoang-nan*. In this category I would place *lichen planus*, *lichen scrofulosus*, *erythema nodosum*, *herpes zoster*, *pemphigus* and *ecthyma*.

Chronic ulcers are often very notably improved by the administration of *hoang-nan*. The circulation of the diseased tissue is quickened, the lymphatics stimulated, and the granulations take on healthy reparative action. While this remark applies to those ulcers which have assumed a

chronic form owing to unhygienic surroundings, filth, cold, hunger or dissipation, I have had no reason to believe that hoang-nan is at all more efficacious in open cancer than the numerous other remedies which have been tried and found wanting. But in scrofula it has yielded very excellent results. Eczema as it occurs in scrofulous children has often been improved by a resort to the subject of this paper. It is, however, in the chronic adenitis characteristic of the disorder and in the ulcers left after the complete degeneration and evacuation of glands that I have especially seen the most favorable influence exerted. In syphilitic lesions likewise I have quite often availed myself of the tonic properties of the drug with satisfaction to myself and advantage to my patients. As we all know, there are epochs in the progress of syphilis when the impoverished blood, enfeebled appetite and digestion, inactive liver and swollen spleen—in brief, profound deterioration of systemic nutrition—call imperatively for relief and suggest an addition to or even an entire suspension of routine antisyphilitic medication. The fact, as I have said, is sufficiently well recognized, and yet it appears to be too often overlooked or neglected in actual practice. Marked constitutional depression due to the disease may be observed at all stages, but is more common in the later. The initial sclerosis, however, may take on unhealthy inflammation attended by severe constitutional reaction. The stomach becomes rebellious, the digestion much enfeebled, the liver inactive, the bowels capricious. In this state of affairs the exhibition of mercury or iodine will frequently prove prejudicial. Either will aggravate the digestive distress, act as a local irritant and seem a poison rather than an antidote. The same process, manifested by the same general disturbances, may show itself in the primary adenopathy. The later cutaneous lesions of the secondary stage, the development of gummy tumors and invasion of the viscera during the tertiary period may also, not seldom, be productive of a general condition in which, for a time, specific treatment will be of no avail or even work mischief. The later exceptions, also, often occur in conjunction with a general depraved condition of fluids and solids. The scaly syphiloderm, the pustular, the ulcerated tubercle, syphilitic ecthyma, rupia, extensive ulcerations of mucous membrane; each and all of these phases may necessitate the resort to tonic measures and the partial or complete suspension of specific remedies. When, under a tonic regimen, an appetite has returned, when the stomach has regained its power, the bowels and the kidneys act with regularity, when the liver has become capable of performing its functions, the specific drugs may be resumed with advantage. It is needless to dwell upon the circumstance that these unamenable cases usually develop in such persons as have abused their vital

resources by sexual excess, intemperance, continuous feverish anxiety regarding business matters, and the many other ways in which modern men "burn the candle at both ends." When it is judicious to do away with mercurials and iodides I have found much satisfaction in the employment of hoang-nan. It may be used alone or combined with iron and quinine or, if need be, cod-liver oil. This tonic treatment of syphilis is, I believe, too much neglected. I have not the slightest intention of detracting from the value and the necessity, in the vast majority of cases, of the approved mercurial or mixed plan of treatment, yet I am firmly convinced that there are times when this plan is harmful instead of beneficial, and to recognize such periods in the progress of the affection is no less necessary than to make the diagnosis that the disease is actually present. In fact, the recognition when to vary the specific by a tonic course is a sound evidence of the physician's power of discrimination.

#### GLANDULAR HYPERTROPHY AT THE BASE OF THE TONGUE AND ITS TREATMENT.

BY JOHN O. ROE, M.D.,  
OF ROCHESTER, N. Y.

It is not unfrequently the case that many of the minor localized affections that give rise to a variety of disturbances, are not only entirely overlooked, but remain unsuspected. This has, to a great extent, been the case with the glandular hypertrophy which is of frequent occurrence at the base of the tongue; and it is not until recently that the importance of this diseased condition has been fully recognized.

In the pharynx and naso-pharynx are found collections of mucous and lymphoid glands which are aggregated into various masses at certain points. To these masses have been given the general name of tonsils. They are, however, further specialized as follows: the collection between the pillars of the fauces is termed the "faucial tonsil;" the mass in the vault of the pharynx, the pharyngeal, or "Luschka's tonsil;" while the mass collected together at the base of the tongue is termed the "lingual tonsil."

The glands composing these various tonsils are exactly identical in their structure, and have the same functions to perform. The chief function which these glands perform is unquestionably the secretion of mucus for the purpose of keeping moist the lower pharynx.

The upper pharynx, which constitutes a portion of the respiratory passages, is covered with columnar epithelium, and is abundantly supplied with muciparous glands for the purpose of modi-

fying the air in its passage to the lungs; while the lower pharynx, which constitutes a portion of the food tract, is covered with squamous epithelium and is very scantily supplied with muciparous glands, and hence arises the necessity for a lubricant for the pharynx from another source.

In addition to the secretion of mucus, important functions are attributed to the lymphoid tissue found in these masses. These are: first, the prevention of fluid waste in the economy, by reabsorbing the buccal secretions, particularly in the intervals of deglutition; secondly, the absorption from the food bolus in its passage over them of certain nutritious elements; and thirdly, the performance of a certain office in the blood manufacturing system, acting, as Hingston Fox expresses it, "as nurseries for young leucocytes planted by the water side and drawing their sustenance from the nutrient stream." ("The Functions of the Tonsil," *Jour. Anat. and Physiol.*, London, 1885-6, vol. xx, p. 559.)

This glandular tissue is moderately supplied with blood vessels, and it is surrounded by a network of these vessels more or less spread out over the base of the tongue.

Subject as this tissue and these blood vessels are to all the variations of the temperature of the fluid and solids that pass over them, and to the direct effect of many of these substances that tend to irritate the tissue and to cause engorgement of the blood vessels, it is not surprising that abnormal conditions of these parts are frequently found.

It is, therefore, almost invariably the case that associated with a hypertrophied condition of this glandular tissue is an abnormally distended condition of these blood-vessels. And it is the varying degrees of the distention of the blood-vessels supplying this glandular tissue and of those surrounding it, which account for the varying degrees of enlargement or projection of this glandular tissue and the different appearances that these parts present on inspection at different times. The condition of this tissue and of these blood-vessels, therefore, not only varies with the condition of local irritation, but also with plethoric conditions of the general system.

The chronic engorgement of these vessels may also be, as Mr. Lenox Browne states, "symptomatic of mitral insufficiency or of severe hepatic derangement or even of cerebral lesion."<sup>1</sup> The veins of this region are frequently found so much dilated as to be really varicose, and sometimes to approach a hæmorrhoidal condition. The frequent occurrence of the spitting of blood by persons having an irritable throat, is due very often to small ruptures or leakages of these distended and weakened vessels.

It is very common to find hypertrophy of the glandular tissue and enlargement of the vessels at the base of the tongue associated with a similar

condition of the faucial and pharyngeal tonsils, and also with a chronic follicular pharyngitis. The symptoms of hypertrophy of the lingual tonsil in many respects resemble those produced by hypertrophy of the faucial tonsil. It has a marked interference with phonation, producing a guttural intonation, as if an obstruction existed in the throat. In the effort to overcome this obstruction, the patient soon experiences the sensation of vocal fatigue.

The glandular hypertrophy at the base of the tongue is frequently the cause of the great variations from day to day in the singing voice, and is the reason why some singers are able to sing in a clear voice only after a period of rest. I have observed this condition to be the cause of a number of cases of vocal failure in singers, due, as has been observed by Dr. Holbrook Curtis,<sup>2</sup> to direct mechanical obstruction to the free opening of the epiglottis or to a reflex action exerted on the motor laryngeal nerves. The epiglottis, in these cases, is not only greatly hindered in its movements, but the irritation of its upper portion I have observed to be the cause of many cases of chronic laryngeal hyperæmia and hoarseness, and also of peculiar spasmodic and persistent coughs, as has been observed by Dr. Rice.<sup>3</sup>

This condition of glandular enlargement is also sometimes the cause of bronchial irritation and asthma.

The sensation experienced by the patient is that of fulness, or of a foreign body in the throat, as for example, some short substance, or a hair; some patients liken it to a rag or a piece of thread, and they are continually trying to get rid of these apparent obstructions by the effort of hawking, or swallowing.

These glands are also subject to frequent exacerbations of acute or subacute inflammation, as is the case with the faucial tonsils; and this condition is the cause of dysphagia and pain in the throat extending up the sides of the throat to the ear, as observed by Dr. Glutsmann.<sup>4</sup>

The condition known as "globus hystericus," frequently observed in females, was first demonstrated by Mr. Lenox Browne to be due to a condition of engorgement of these glands and blood-vessels at the base of the tongue, which may become enormously engorged by the reflex irritation of uterine or ovarian disorders. (Compté-Renan, *Congress International de Laryngologia*, Milan, 1880, p. 48.)

The diagnosis of these diseased conditions is very easily made by drawing the tongue forward with a napkin and inspecting the base of the tongue by the aid of the laryngeal mirror.

In the treatment of this condition we have two primary objects to be accomplished: first, the

<sup>1</sup> New York Medical Journal, Nov. 8, 1884, Vol. x1, p. 510.

<sup>2</sup> The Medical Record, New York, May 1, 1886, Vol. xxix, p. 493.

<sup>4</sup> Medical Record, New York, Dec. 17, 1887, Vol. xxxii, p. 757.

removal of all the tissue that has become hypertrophied; and, second, the obliteration of varicose or distended blood-vessels.

The removal of this tissue is quickly and most easily accomplished by simple abscision with a curved knife, or a pair of curved serrated scissors, cutting it down to its normal level. This operation is usually attended by very little bleeding, the tongue heals quickly, and with but little soreness. In cases in which the tissue can be readily engaged in the loop of a cold wire snare, this method of removal I have also found to be very excellent.

The galvanic cautery is also very useful in cases where this enlarged tissue is much flattened and where it is unusually vascular.

Corrosive substances are also recommended, as chromic acid, nitric acid, mono-chloroacetic acid, Vienna paste, fused nitrate of silver, etc. In conditions of a very moderate amount of hypertrophy, two or more applications of these stronger caustics may be sufficient to remove all the tissue desired. But when any great amount of hypertrophy is present, their employment is as unadvisable as they ordinarily are in the same condition of hypertrophy of the faucial tonsils, since applications of these substances have to be repeatedly made in order to produce the desired amount of destruction of tissue, and the patient is subjected to an amount of pain and discomfort that would seem almost unwarrantable when the tissue can be removed in mass by simply cutting it away.

In those cases in which it is desirable to remove the hypertrophy with the galvanic cautery, there are three methods of doing it. The first is to destroy the whole growth by burning it away with a flat cautery point from the summit downward; the second is to cut it off at the base with an ordinary cautery knife; the third method is to transfix the growth through the base, by means of a very slender cautery point.

For the destruction of the enlarged blood-vessels or varicose veins, the galvanic cautery point is the instrument to be employed, and we can accomplish the same result by no other method with so much ease and precision. A slender cautery point should be used, and this should be applied longitudinally to the trunk of the vessel to be obliterated. It is desirable in the destruction of these vessels to obliterate them as near as possible to the point where they arise; it is, however, often necessary to obliterate them at different places for the reason that they so frequently anastomose with each other.

Before attempting any of these operations, however, cocaine should be thoroughly applied. It removes the sensibility of the part, and at the same time it is a marked hæmostatic, as it also is in operations on the faucial tonsil.

Accompanying the removal of these abnormal

tissues at the base of the tongue, attention should be directed to the general conditions of the system, which may have been the predisposing or exciting cause of the local disorder.

DR. J. SOLIS-COHEN objected to the term tonsil as applied to collections of lymphoid tissues other than those existing between the arches of the palate. He highly approved of the writer's method of getting rid of large masses with curved serrated scissors. In cases of slight enlargements he found solutions of creosote in carbolic acid and iodine in glycerine sufficient topical treatment. He would state that in the majority of cases seen by him, and they are counted by hundreds, he found no abnormal dilatation of the veins except in cases of very marked hypertrophies.

DR. GREEN V. WOOLEN, of Indianapolis, said: I am pleased that Dr. Cohen has called attention to the use of the term tonsil, because it relieves me from reproach for saying at my home that there is no such thing anatomically as a tonsil. When once it is known that such is the case we will be free from annoyance and opposition when we desire to remove them. My statistics show that less than 50 per cent. of diseased throats have tonsils and frequent observations show them rare in those not claiming to have diseased ones.

DR. J. ROE, after the discussion of his paper, said: If I were the author of the term tonsil, as applied to the collections of glandular tissue in the throat, I would gladly comply with Dr. Cohen's desire to have the term stricken from our nomenclature. In my paper I have simply stated that the collection of glandular tissue at the base of the tongue is sometimes called the lingual tonsil because of its identity in function and structure with the faucial tonsil. The term tonsil has doubtless been adopted because it is short and easy to use, and at the same time designates the part referred to just as clearly as the longer and more scientific term.

Regarding the statement made by Dr. Woolen, which has already been made by Dr. Bosworth, that normally there are no tonsils, that the enlargements we call tonsils are in reality abnormal conditions. This statement is in the main true. Normally the collections of glands at these points are not noticeable on inspection of the throat, and, therefore, no tonsils appear to exist. Notwithstanding this the same number of mucous and lymph glands are found in these regions as when the tissue composing these glands have become more or less hypertrophied or enlarged by disease.

## FIVE HUNDRED DELIVERIES WITHOUT DEATH IN THE PRESTON RETREAT.

*Read in the Section of Obstetrics and the Diseases of Women, at the Fortieth Annual Meeting of the American Medical Association, June, 1880.*

BY JOSEPH PRICE, M.D.,  
OF PHILADELPHIA.

In making this report I desire to call attention to the accommodations of the Preston Retreat, and its routine treatment of puerperal cases, rather than make a minute analysis of a large number of cases.

The 500 cases reported date from the last death occurring in the Retreat, more than five years ago, and include 275 confinements under Dr. Goodell's care before his resignation as physician in charge. The series had extended to nearly 600 cases before the first death occurred, during my service as physician in charge. Between these deaths there has not been a case of puerperal septicæmia in the institution. Both of these deaths being from puerperal eclampsia in patients suffering from chronic Bright's disease.

The Retreat is a maternity hospital endowed by the will of Dr. Jonas Preston to furnish accommodations for poor, respectable, married women during their lying-in period. The building, standing in an open square of ground, is especially adapted to its purpose. Lying-in wards are entirely shut off from the main building; the delivery rooms, the closets and bath-rooms. The bath-rooms and water-closets are placed in towers at the rear of the building. The plumbing is as nearly perfect as modern sanitary science can make it.

Verandas, enclosed in glass, form large, light, airy corridors about the sides and rear of the building, and furnish a distinct circulating atmosphere between the house proper, the wards and the water-closets.

Wide corridors run through the main building at right angles. This arrangement, together with that of the flues and heating apparatus, makes the ventilation of the entire building simply perfect. The building is heated by the indirect steam method.

The great success attending the work of this maternity is due to the strict enforcement of the law of cleanliness. Cleanliness, water, soap and pure air are still the best antiseptics. Everything and everybody is clean, and jealously kept so. The routine treatment of patients is as follows:

The patient on entering the house is given a hot soap bath, dressed in clean clothing and assigned a clean bed in the waiting ward. If necessary, a laxative is given and the bowels are kept soluble during her waiting period. Thereafter until her confinement she is obliged to take at least two hot soap baths per week and wear clean clothing. She is allowed to do such light work about the house as the physician may deem advisable and is encouraged to take as much open air exercise as circumstances will permit. Every

effort is made by the officers and employes of the institution to make it as cheerful and homelike as possible. When ready for the delivery room, the patient is again given a hot soap bath, also an enema and vaginal injection of a 1 to 2,000 solution of bichloride of mercury in distilled water. She is clothed in a clean night-robe and drawers and placed upon a new, clean delivery bed. Scrupulous cleanliness is observed in all manipulations of the patient, and after delivery a second vaginal injection is given and a vaginal suppository of iodoform is introduced.

The patient's person is carefully cleaned, all soiled clothing removed, the binder and pad applied, a clean set of night clothes put on, and the patient is put in a new, clean bed in the ward. All soiled articles are immediately removed from the delivery room and a new bed made up for the next patient.

The patients in the ward are carefully observed by the nurses, but no unnecessary handling or interference permitted; they remain in the ward until they are able to be up, when they are removed to the convalescent ward. As the ward is emptied, the beds are burned and all bedding most carefully cleaned.

No soiled linen (as draw-sheets, diapers, napkins or other articles) is allowed to remain in the ward; but when soiled is immediately placed in a covered receptacle and removed from the building. No sponges, wash-rags or absorbent cotton are used in the house. Corrosive jute supplies the place of these articles, being clean, soft, remarkably absorbent and cheap. It is destroyed immediately after being used. The pads to absorb the lochia are also of jute and likewise destroyed. The beds in the ward are of fresh rye straw and are burned after ten days. All discharges from the delivery room are immediately burned; all bedding soiled beyond cleansing or contaminated by purulent or specific discharges is likewise burned. In short, every effort is made to keep the house perfectly pure and sweet.

The arrangement of the building permits of rotation in the use of the wards, so that a ward once emptied is not again used until three others have been filled. In the meantime it is most carefully cleaned and thrown open to the atmosphere. A similar system is pursued in the convalescent wards and delivery rooms.

In the 500 labors reported, there were 200 primiparous mothers. The complications were as follows: There were 52 forceps deliveries, most of them for contracted pelvis and large, hard heads; 3 induced labors; 3 cases in which podalic version was performed; 2 cases of missed labor; 1 case of congenital absence of the right leg of the mother (a normal delivery); 1 case of placenta prævia; 12 still births; 3 twin labors; 5 breech presentations and 1 face presentation. Other statistics are omitted purposely.

## TUBERCULOSIS OF BONES AND JOINTS.

*Read before the Chicago Medical Society,*

BY CHRISTIAN FENGER, M.D.,  
OF CHICAGO, ILL.

*History.*—The tuberculosis of bones and joints form anatomically and clinically a unit, because the tuberculosis of the bones usually extends to the joints, and derives from the affections of the latter the main clinical features.

Our knowledge of this branch of tuberculosis is only twenty years old, commencing at the time when Karl Küster called attention to the frequent occurrence of miliary tubercles in the fungous granulations of the disease then known as white swelling. Soon afterwards Friedländer, Hueter, and especially Volkmann and König, not only verified Küster's statements, but carefully studied anatomically, clinically and experimentally this form of local tuberculosis. This naturally attracted the universal attention of the profession, so that an extensive literature of the subject quickly sprang up—so quickly, indeed, that even before Koch's discovery of the bacillus tuberculosis, in 1881, the tuberculosis of bones and joints was already well established as a distinct form of disease. So much was this the case that Volkmann, at the German Surgical Congress in 1885, was able to state that all cases of the hitherto so-called paidarthrocacis, spina-ventosa, tumor albus, fungous and strumous arthritis, etc., belonged to tuberculosis.

*Etiology.*—Tuberculosis of bones and joints is evidently always a secondary invasion; that is, the place of primary invasion of the bacillus must be elsewhere in the body, and one or more dépôts must exist in the lungs or lymph glands before so deep-seated localities as the bones and joints can be invaded. When, therefore, authors speak of primary tuberculosis of the bones and joints, it is only a clinical term and means that clinical examination, or even the autopsy, fails to reveal the place of invasion, the primary dépôts. As a clinical distinction its importance lies in the fact that if tuberculosis is practically localized to a joint, the patient's life is not in danger from deposits in other organs, and the total removal might prove efficient to extinguish the disease.

In this sense a primary, or, to use the more correct expression, a localized articular and osseous tuberculosis, is, according to Kümmer, found in about 40 per cent. of the cases. In the remaining 60 per cent., dépôts are found at the same time in other organs of the body. The lungs come first with 25 per cent.; other joints, 10 per cent.; bones, 10 per cent.; glands, 10 per cent.; peritoneum, 3 per cent.; pleura, 2 per cent.

The presence of the bacillus of tuberculosis in a body is the *condition sine qua non*, and may be aided by other etiological elements, the most important of which is traumatism. Max Schüller

proved experimentally in animals infected with tuberculosis (for instance through the respiratory tract) that a slight traumatism to a joint would determine the localization of the bacillus tuberculosis, by way of the circulation, to the place of traumatism, and that a tuberculous synovitis or panarthritides would follow.

Clinically the tuberculosis of joints has been traced in 56 per cent. of the cases to traumatism, by a direct blow to a joint, or distortion, or over-exertion. It is characteristic that the traumatism is always slight; a severe trauma, causing intra-articular fracture, is very rarely followed by tuberculosis.

As a general characteristic of the articular and osseous tuberculosis it must be stated that it belongs to the benignant chronic forms of disease; that is, it lasts for years and years, has a tendency to spontaneous recovery, little tendency to generalization and, consequently, to the destruction of life, as compared with the acute forms of tuberculosis of the internal organs, or even the experimental inoculated tuberculosis.

An explanation of this clinical fact is given by Baumgarten, who distinguishes between three forms of miliary tubercles:

1. The lymphoid-celled tubercle, Virchow's small-celled tubercle, which is rich in bacilli, extremely malignant, and is found in tuberculosis miliaris acutissima, for instance in the lungs.

2. The mixed tubercle of lymphoid cells and epithelioid cells, which contains fewer bacilli, is less benignant, and is found in the more chronic forms of general miliary tuberculosis.

3. The epithelioid and giant-celled tubercle, with no lymphoid cells, containing comparatively few bacilli, more benignant, and found in the benign forms of localized tuberculosis, joints, bones, lupus and lymph glands.

That this benignancy of the tubercle can be dependent upon lessened vitality in the tubercle bacillus has been proven experimentally by the inoculation of artificially weakened cultures, which were seen to produce localized tuberculosis in the nearest lymph glands only, with no generalization (Baumgarten). Kümmer found heredity as an element in 37 per cent. of the cases.

*Anatomy.*—Tuberculosis has a distinct predilection for the medullary tissue of the bones; thus it is correct to speak of the tuberculous osteo-myelitis as a first effect of the arrest of bacilli in some place of the medulla. The anatomical condition of the vessels in this tissue, thin walls, slight contractility and sluggish circulation, favor the implantation on the vessel wall, in the same way as pus microbes are localized in acute osteo-myelitis.

Embolism from foci in the lungs opening into the pulmonary veins may cause a tuberculous infarction of the bone. The interesting experiments of Müller, who injected pus from a tuber-

culous abscess into the nutrient artery of the long bones of goats and rabbits, have proven that this is a possible origin of local osteo-tuberculosis.

The seat of the tuberculosis in bones is usually in the cancellous substance of the epiphysis of the long bones, the short and flat bones, and very seldom, the medulla of the shafts. The only exceptions to this are the shafts of the phalanges of the fingers and toes, and the metacarpal and metatarsal bones in children, where the tuberculous osteo-myelitis gives rise to the well-known spina-ventosa of the old authors.

The frequency of the localization in the different bones of the body is given by Schmalfuss, as follows:

Billroth.	Jaffe.	Per cent.	Schmalfuss.	Per cent.
Vertebra	Vertebra	26	Knee	23
Knee	Foot	21	Foot	19
Cranium	Hip	13	Hip	16
Face	Knee	10	Elbow	9
Hip	Hand	9	Hand	8
Sternum-Ribs	Elbow	4	Vertebra	7.5
Foot	Pelvis	3	Tibia	4
Elbow	Cranium	3	Cranium	4
Pelvis			Pelvis	3.6
Tibia and Fibula	Sternum, Clavicle and Ribs	3	Sternum, etc.	3.6
Femur	Shoulder	2	Femur	1.9
Shoulder	Femur	1	Shoulder	1.5
Humerus	Tibia	1	Ulna	1.4
Ulna	Fibula	1	Humerus	1
Radius	Humerus	1	Radius	0.7
Scapula	Scapula	0.6	Fibula	0.5
	Ulna	0.6	Patella	0.1

The gross appearances of the osteo-tuberculosis as it is found in the articular extremities of the long bones are well described by König under the three following forms: (1) The granulating focus; (2) the tubercular necrosis, and (3) the tuberculous infarct, the diffuse tuberculous osteo-myelitis.

1. *The granulating focus* is found as single or multiple, round or cylindrical cavities, from the size of a millet seed to that of a pea or hazelnut, and contains either grayish-red, soft, living granulation tissue, or, if coagulation necrosis has taken place, yellowish-gray cheesy matter or liquid tuberculous pus. Fine spicula of bone may be felt with the finger, or when smaller, seen with the microscope in the contents.

The granulation tissue contains epithelioid and giant-celled tubercles and bacilli. The wall of the cavity is either soft, when rarefying osteo-myelitis has taken place, significant of destruction and extension; or sclerotic when an osteo-plastic osteo-myelitis surrounds the focus, showing a tendency to localization and cicatrization. As little as this form of osteo-myelitis has in common with the usual form of acute osteo-myelitis due to pus microbes, with its extensive area of inflammation and large sequestra, still it may be difficult to distinguish it from the more rare form of sub-acute multiple osteo-myelitis of the epiphysis, in which multiple foci of similar form are found. But the infectious osteo-myelitis has thin

yellow pus and flabby granulations without tubercles, and the pus contains pus microbes.

2. *The tubercular necrosis.* When the area of the tuberculous osteo-myelitis is larger than a hazelnut, the bone is usually not absorbed, but remains as a sequestrum in the cavity. This sequestrum is sometimes osteo-sclerotic, sometimes osteo-porotic, sometimes like the surrounding bone, according to the character of the osteo-myelitis previous to the interruption of nutrition. It is yellowish-white or grayish-red, according to the contents of the Haversian canals or medullary spaces of dead or living tuberculous tissue. It may be separated from the wall of the cavity by a layer of tuberculous granulation tissue, or dry cheesy matter, or tuberculous pus. If separated by a layer of granulation tissue, this may be so thin that the sequestrum fits the cavity exactly, and, if its shape is irregular, fits in so immovably that it takes a good deal of force to pry it out by the gouge and chisel.

3. *The tuberculous infarct* has the characteristic conical shape of infarcts in other parts of the body, with the apex in a proximal and the base in a distal direction. It represents the territory of an artery and suggests embolism. Large infarcts, then, must require either a larger embolus, or, in addition to the embolus, arterial thrombosis, from the place of arrest of the embolus. Their seat is usually a little inside of the cortical substance of the bone; thus, they may be overlooked if the bone is not sawn through. If, as in the specimen here presented, the base takes in the articular surface of the joint, this surface will be ground off and polished, signifying instantaneous death of the infarct at the time of the embolism.

The line of demarcation forms slowly as a furrow surrounding the dead area, the central portion of which may remain in connection with the living bone for a long time, a year or more, even in a joint apparently on the way to recovery.

The smallest sequestra, in the dry forms of tuberculosis with a tendency to cicatrization, may heal in or be imbedded in the non-tuberculous cicatricial tissue, remaining after the tuberculosis has come to an end and incomplete recovery taken place, without perceptibly disturbing the function.

The fate of the osteo-tuberculous foci varies according to the activity of the microbe and the size of the focus. The smaller granulation foci in the dry forms of tuberculosis may result in either complete recovery by removal of the tuberculous elements by absorption and filling up the cavity with cicatricial tissue, or in incomplete recovery, in which part of the focus is transformed into cicatricial tissue, in part of which dormant bacilli remain. These are apt to be revived under favorable circumstances, of which a fresh culture fluid from a traumatism is the only one known.

In the joints, however, this is a very common occurrence, as we shall see later on. This accounts for the local relapses so frequent in tuberculosis as to make a permanent recovery almost impossible.

Small sequestra may, as stated above, disappear by absorption, or be included in the cicatricial tissue. Large sequestra will, of course, neither be absorbed nor be included in a cicatrix. Moreover, they furnish an inexhaustible depôt of bacilli and keep up the local tuberculosis on its progressive way to further destruction.

We have hitherto considered the osteo-tuberculosis at its place of origin in the bone, where it is of comparatively little importance, since so long as it is confined to the bone it gives rise to little or no functional disturbance. We shall now follow it on its extension beyond the bone, and then distinguish between its extension to the periosteum and the soft tissues on the one hand, and to the joints on the other. It is not until the tuberculosis has extended to one of the places named, that its symptoms become manifest and the grave consequences to the patient's welfare take place.

1. *Extension to the periosteum outside of the joints.*—It is characteristic of tuberculosis that the periosteum, on the whole, is rarely affected to any great extent. We do not find, as in acute osteo-myelitis, a diffuse infiltration of the periosteum and the formation of extensive masses of bone. Tuberculosis of the periosteum is localized in the joint in the same way as in tubercular osteo-myelitis, and the place of perforation limited to a small area surrounded by normal periosteum, with little or no thickening or enlargement of the bone affected. When the dry granulating form of tuberculosis reaches the periosteum a small, soft, elastic, limited granulation tumor forms, first under the periosteum, then outside of it. It is characterized by slow growth, comparatively little pain, slight tenderness, and a tendency to remain stationary for a long time. It is different with the soft suppurating tuberculosis, which, although it also breaks through the periosteum in a limited space, acts in an entirely different way as soon as it has reached the para-periosteal loose, connective-tissue spaces. Here it has a tendency to extend rapidly and to form large abscesses, the so-called cold abscesses, traveling, like all other abscesses in connective tissues, in the direction of least resistance. On its way from the deep para-periosteal tissues out toward the skin, it forms large or small abscess cavities and finally breaks through to the surface, after having transformed the skin into tuberculous tissue, which sometimes presents the appearance of lupus at the place of perforation. No conclusion can be drawn from the size or acuteness of the abscess as to the extent of the osteo-tuberculosis. A large abscess may come from a small focus in the bone, and *vice versa*.

The question has arisen whether the rapid formation of tuberculous abscesses is not the consequence of a mixed infection from auto-infection of pus microbes. It must be said that such auto-infection is rare, as the pus in these abscesses is found on microscopical examination and culture in culture substances, not only not to contain pus microbes, but its inoculation in the camera anterior of the eye, or the abdominal cavity of animals, produces an unmixed tuberculous invasion and no suppuration.

*Diffuse tuberculous osteo-myelitis.*—This form is rare. On the cut surface of the bone we find large, irregular, often multiple areas and islands, with no tendency to definition, of a yellowish-white infiltration, containing small multiple foci of liquid pus. Here is no tendency to limitation or the formation of sequestra, but rather a tendency to spread indefinitely and to invade even the medullary tissue of the shafts. This form has in common with the acute diffuse osteo-myelitis that it will spread through the Haversian canals diffusely to the periosteum and cause a diffuse plastic periostitis with irregular diffuse masses of bone formed on the outside of the cortical substance. Consequently it resembles, in its clinical features, acute osteo-myelitis. Locally and generally it is a severe form: locally it forms an extensive tuberculous depôt, from which abscesses may form indefinitely; generally, patients with this form are exposed to the dangers of a fatal general tuberculosis if the whole depôt is not removed in time. In operating it is important to recognize this form, since it requires more radical measures, either amputation or very extensive excision. As a rule, the mere removal of the periosteal tuberculous masses and the diseased medullary tissue is insufficient, and the whole continuity of the bone must be taken away, as in the specimen here presented. Fortunately this form is extremely rare.

*Tuberculous abscess.*—In addition to what has already been stated about the tuberculous abscess I shall here briefly call attention to the main characteristics of its wall, which is formed of a thinner or thicker layer of tuberculous granulation tissue thickly studded with the characteristic miliary tubercles of the benignant type, with relatively few bacilli. This tuberculous pyogenetic membrane, as it was called by the old authors, is only very loosely connected with the surrounding tissues and organs, in the spaces between which it is located. So loose is the connection that, when the abscess is opened, the whole membrane can be wiped off the wall with a sponge, or, when more firmly attached, easily removed with a sharp spoon, leaving the walls so healthy as to readily unite by first intention when brought together; hence the modern treatment of these abscesses by incision of the whole length, removal of the wall, and reunion. In

rare instances, however, a fascia, for instance the fascia lata of the femur, may be diffusely infiltrated, even to such a degree as to cause diffuse necrosis, presenting the appearance of diffuse phlegmonous inflammation. In such cases careful removal, by the knife and scissors, of the whole area involved is required.

At this place I will call attention to the latest step in the conservative treatment of large tuberculous abscesses, especially the large psoas abscesses from tuberculosis of the vertebral column from Pott's disease. It is well known that the opening of these abscesses in *præ*-antiseptic times was almost always followed by a fatal septic infection from without. The modern opening and drainage under antiseptic precautions, so much praised in the beginning, has been proven not to be without danger, inasmuch as, in many cases, late infection has taken place when, after months, the inclosed fistulous openings have been guarded with less stringency in the application of antiseptic dressings.

Thus, two years ago, Bruns, in Tübingen, proposed a return to the older subcutaneous method, namely aspiration; but, in addition to this, injection into the emptied abscess cavity of a 10 per cent. iodoform emulsion in equal parts of glycerine and alcohol, this procedure to be repeated every four to six weeks. Usually, after three or four aspirations, the formation of pus in the abscess cavity ceases, the fever stops, and the patient regains health and strength. No iodoform poisoning from this treatment has yet been reported.

2. *Extension into the joints.*—The osteo-tuberculous foci in the epiphyses of the long bones are situated so near to the surface of the joint that, when they come to the surface, in an overwhelming majority of the cases, they will be inside of the articular cavity; the bacilli of tuberculosis are consequently poured into the joint, and a tuberculous synovitis or arthritis is the result.

Tuberculosis of joints is by far the most common joint disease, so much so that König states that, in the surgical clinics, the surgeon will have 100 cases of tuberculosis of the joints to deal with to one of the other classes of inflammation, such as gonorrhœal, syphilitic, septic, osteomyelitic, rheumatic, or the metastatic inflammations subsequent to acute infectious disease. Although the statement may seem to the general practitioner to be carried to the extreme, still the authority of König is sufficient warrant for the statement that tuberculosis as a cause of joint disease far exceeds all others, and that the tubercular arthritides are the everyday cases of the surgeon.

We distinguish, as to origin, between primary synovial and primary osteal tuberculosis of the joints. Max Schüller stated, as a result of experiments, that a slight injury to a joint in a per-

son who had bacilli floating in his blood would determine localization, commonly in the form of a synovial tuberculosis. It may be said here that, as to the relative frequency of the two forms, it has been shown that the primary osteal tuberculosis occurs two or three times as often as the primary synovial. As far as the course and development of the articular tuberculosis is concerned, the difference in origin makes little or no difference—so little, indeed, that we are unable to make a differential diagnosis, even from the symptoms.

As to the primary osteal tuberculosis of the joints, we have already seen that an osteo-tuberculous infarct is located in the joint from its very beginning, while the smaller granulation foci open into the joint secondarily. When located close to the articular cartilage, this must be destroyed before the joint is invaded, the cartilage forming a barrier which may sometimes prove sufficient to resist invasion. A small dry granulation focus may heal up before perforation takes place.

When located at the surface of the joint, where the bone is not covered with articular cartilage, the thin periosteum and the serous membrane covering it are more easily opened through. An important complication is when an osteo-tuberculous focus is placed right at the insertion of the capsule of the joint. It may then open in and outside of the joint simultaneously, or the one or the other, the saving of the joint depending upon the few lines of difference. When the tubercle bacillus invades a joint and tuberculosis of the joint ensues, all the constituent parts of the joint will be successively affected, namely, the synovial membrane, para-synovial tissue, ligaments and peri-synovial tissues, the articular cartilage, and finally the articular surface of the bone.

It is a question whether so light a form of inflammation as a simple synovitis (whatever that may be), as mentioned by Kümmier, can set in as an effect of either ptomaines alone, from a near focus, or from extremely weakened tubercle bacilli. A simple serous synovitis of entirely benign character, if it exist, is of extremely rare occurrence.

Commonly the presence of the tubercle bacillus in the joint produces one of the following forms:

1. A pannous hyperplastic synovitis. 2. A tuberculous hyperplastic synovitis or papillomatous plastic synovitis. 3. A granular or fungous hyperplastic synovitis (Hueter); and, 4. The tuberculous articular empyema (König).

1. *The pannous hyperplastic synovitis (Hueter).*—The synovial membrane is moderately thickened. From the border of the cartilage a thin vascular layer of granulation tissue creeps in over the surface of the latter, so much so as to sometimes cover the larger part of the surface

and unite with the cartilage, which gradually becomes transformed into connective tissue. The tubercles are usually not visible to the naked eye.

2. *The tuberculous plastic synovitis, or circumscribed nodular tuberculosis of the synovial membrane.*—The tubercular fibroma is characterized by the development of a subserous tumor the size of a walnut or larger, protruding into the joint and filling, for example, the supra-patellar recess of the knee-joint, with simple synovitis or pannous synovitis in the rest of the cavity. Such a local tuberculosis is amenable to extirpation of the tuberculous tumor followed by recovery. The papillomatous plastic synovitis is a diffuse form of hyperplastic tuberculosis, and, as shown in the specimen, we find the whole inner surface of the synovial membrane covered with sessile or pedunculated papillomatous growths, small and rather uniform in size, some of which may become detached and constitute the so-called rice bodies.

3. *Diffuse granulating synovial tuberculosis.*—Here the synovial membrane is considerably thickened, hyperæmic, with or without visible tubercles, always accompanied by invasion of the para-articular tissue and the ligaments of the joint. Thus is formed the thick œdematous mass of tissue, usually of a gelatinous appearance, in which coagulation necrosis will cause, in the more dry forms, islands of cheesy matter; in the more liquid forms, islands of pus, that is, small multiple abscesses.

Any of the above named forms of synovitis may give rise to the exudation of serous or sero-fibrinous fluid in the joint, the tuberculous hydrops of König. A considerable hydrops is most commonly associated with a diffuse synovial tuberculosis, with little thickening of the capsule. Less commonly it is found in the tuberculous and papillomatous synovitis; most rarely in the fungous or granulating synovitis. The fluid is clear in the lighter forms; slightly milky from migratory corpuscles, or mixed with shreds of fibrin in the severer forms. So-called rice corpuscles may be found and derived either from islands of fibrin or from loosened papillomata. Their presence indicates tuberculosis (Reidel).

4. *Empyema articulationis tuberculosum. Cold abscess of the joint (König).*—The inside of the capsule is covered with loosely adherent tuberculous membrane similar to that in tuberculous abscesses, so loosely connected with the capsule as to permit of its being scraped off. The remaining synovial membrane is diffusely infiltrated with miliary tubercles, but only slightly thickened, if at all, because of the non-invasion of the para-synovial tissues.

The articular cartilage plays, as a rule, only a passive part in tuberculosis of the joint, as its fate is destruction or absorption. The cartilage covering a large sequestrum dies off and is me-

chanically detached from the bone in smaller or larger pieces. An osteo-tuberculous focus, when reaching the cartilage, will cause gradual local absorption, and a local, usually round defect, through which red granulation tissue or cheesy matter protrudes. The surrounding cartilage may be entirely normal and efficient for the function of the joint. A primary synovial tuberculosis has a tendency to develop most intensely in the region of the capsule at the circumference of the articular cartilage. From here it has an easier way down into the vascular bone than into the non-vascular cartilage, and extends down between the bone and the cartilage as a tuberculous osteo-myelitis, creating a layer of tuberculous granulation tissue that will detach the cartilage from the bone. Local hyperplastic foci in this granulation tissue may perforate the cartilage in many places, just the same as a primary osteo-tuberculous focus, so that the cartilage presents the appearance of a sieve. Finally either the whole cartilage or shreds of it are found loose in the cavity of the joint.

In the pannous synovitis and the dry forms of fungous synovitis an apparently direct transformation of cartilage into connective tissue takes place.

The articular surfaces of the bone, after the disappearance of the cartilage, present the following appearance: In the dry form, a layer of not very vascular connective tissue covers the surface and connects it with the opposite similarly transformed surface. In the more moist and suppurating forms, a layer of miliary tuberculous tissue covers the bone with visible, yellow miliary tubercles, extending usually only a short distance down from the surface. Thus the whole head of the femur, the acetabulum, etc., is gradually destroyed.

#### SYMPTOMS.

I. *Tuberculous Hydrops*, as we have stated, is common in the diffuse synovial tuberculosis with little swelling of the capsule, also in the papillomatous diffuse synovitis or local tuberculous synovitis, but is seldom found in the granulating fungous synovitis. It is characterized by the usual symptoms of a painless intra-articular accumulation of fluid which usually reaccumulates when removed, and sooner or later, the tuberculosis going on, shows some thickening of the capsule after removal of the fluid.

The prognosis is relatively good because there is little tendency to destruction of the joint or to suppuration. Some cases recover after puncture and rest. Rice bodies, when present, can be felt to give a peculiar friction sound when moved from one point of the joint to another. The joint remains for a long time in relatively good function which only ceases when, later on, thickening of the capsule and destruction of the joint sets in.

A tubercular fibroma can be felt after the aspiration of the joint as a sessile, more or less movable tumor, simulating floating cartilage. Simple arthrotomy and extirpation may prove effectual. The tuberculous hydrops is never accompanied by fever. As above stated, the lighter forms may recover by aspiration and immobilization. More obstinate forms require opening of the joint, excision of the local tumors if found, a partial excision of portions of the capsule with iodoformization and drainage. König has opened the knee-joint on both sides of the patella, excised large slices of the capsule, and seen perfect recovery. However, the result is always uncertain, and the tuberculosis may in spite of initial, more conservative treatment, go on to the severe and more destructive forms, and require more radical operative measures.

II. *Fungous Arthritis, Granulating Synovial Tuberculosis, White Swelling, Tumor Albus.* This is by far the most common form of tuberculosis of the joints, whether primary osteal or primary synovial. No symptoms enable us to make a distinct diagnosis between a primary osteal and a primary synovial tuberculosis of the joint, but as we stated in the discussion of tuberculosis of the bones, the primary osteal form is the most common. In the knee, the proportion of the primary osteal to the primary synovial form is as three to one; in the hip, four to one; in the elbow, four to one (König). As to age, the proportion is in children below 15, two to one; above 15, three to one. If it were possible to know that a large osteo-tuberculous focus was to be found in a given case of articular tuberculosis, this knowledge would determine an immediate operation, and no time would be lost by conservative treatment. But unfortunately, as yet the diagnosis is almost impossible.

The fungous arthritis is much more frequent in the lower than in the upper extremities. According to Albrecht, out of 325 cases, of which he gives the statistics, 91 were found in the joints of the upper extremity, and 234 in those of the lower extremity. The granulating synovitis or fungous arthritis presents a great variety of clinical forms, according to the acuteness of the onset and the course; slowness or rapidity of destruction, and extent of the infiltration of the synovial tissues. It is especially the degree of peri-articular infiltration, its almost entire absence, or presence, in abundance, that makes the clinical distinction between the dry and soft forms so characteristic that Volkmann has called attention to the former as a distinct class of cases.

1. *The dry granulating tuberculosis, the atrophic form, (plastic synovitis) (Kümmer), caries sicca of Volkmann,* so common in the shoulder-joint is characterized by the tendency of the tuberculous tissue to cicatrization, and slight ten-

dency to extensive destruction of cartilage and bone. Absence of invasion of para-articular tissues results in only a slight or in no swelling in the region of the joint, which may even be found atrophic, as in the shoulder-joint from atrophy of the muscles, or in the hip-joint in young individuals (König); more rarely in the knee. In the shoulder-joint there may be considerable atrophy, and still so much mobility that the disease may simulate a neurosis resulting in atrophy of the muscles of the joint. A careful examination *in narcosis*, revealing restriction of mobility from cicatricial contraction of the tuberculous capsule, will enable us to make an early diagnosis, which is confirmed later on when peri-articular abscesses form. In a majority of cases, however, this form has a tendency to come to an end without the formation of abscesses, terminating simply in a more or less restricted mobility of the joint. Dry caries of the shoulder-joint is found not infrequently in young women (König).

2. *Fungous arthritis, tumor albus, synovitis fungosa sive granulosa*, is probably the most common of all the forms of articular tuberculosis. It is characterized by the softer condition of the tuberculous granulation tissue, with tendency to destructive invasion of all the elements of the joint, coagulation necrosis and liquefaction. The invasion of the para-articular tissues causes considerable swelling in the region of the joint, giving to the latter the characteristic spindle-shape so frequently found in the knee, elbow and ankle-joints; the swelling being so much the more apparent when atrophy of the muscles above and below has taken place. Extension of the infiltration from the para-articular tissues out towards the subcutaneous tissues finally causes the swollen joint to be covered with a whitish, immovable, dense skin, giving the joint the appearance from which the time-honored name of white swelling is derived. In the beginning of the disease a slight degree of hydrops is found in a few cases; most often the cavity of the joint contains no fluid, or not a sufficient amount to be recognized by palpation. Later in the disease liquefaction in the islands of coagulation necrosis in the islands of soft granulation tissue gives rise to the presence of tuberculous pus. This may be found as small foci in the soft granulating capsule, small abscesses inside of the granulation tissue, or as pus from the cavity of the joint. At this stage of the disease, especially in the softer form of tuberculosis, the peri-articular abscess is formed. Most commonly a local destruction of the tuberculous capsule facilitates the invasion of the peri-articular inter-muscular spaces by the tuberculous pus already contained in the joint; and a more or less rapid increase in size of the abscess cavity in the direction of least resistance, causes the formation of more or less distant ab-

cess cavities, which of course, always lead into the cavity of the joint. More rarely, peri-articular abscesses form directly from an osteal focus by the extension of a mass of tuberculous granulation tissue, extending through the capsule out into the peri-articular tissue, as a primary mass of solid granulation tissue in which liquefaction takes place secondarily. A peri-articular abscess originating in this way may attain the same size as that previously mentioned, but owing to its original form a local osteo-tuberculous focus is of less prognostic importance, inasmuch as it does not necessarily indicate suppurative destruction of the cavity of the joint. This latter form of abscess may be opened and evacuated and may then close up with or without the removal of the osteo-tuberculous focus and still leave the joint in a more or less unimpaired condition; while on the other hand, the peri-articular abscess communicating directly with the destroyed joint cavity has no tendency to come to a close, but leaves fistulous openings which keep open permanently, and only too often, when not protected by antiseptic dressings, sooner or later, furnish a place of invasion for pus microbes, adding acute supuration or sepsis to the tuberculosis, and giving rise to a rapid increase in the destruction of the articular surface.

A fungous arthritis, when limited to a single joint, will rarely cause any rise in temperature. High temperature is always indicative of a mixed infection with pus microbes, or what is very rarely met with, general acute tuberculosis. By far the most common is the mixed infection which comes from without, the pus microbes entering the open and unprotected peri-articular abscess. It is very exceptional that auto-infection, that is, invasion of a closed tuberculous joint by floating pus microbes from a distant place of invasion, takes place. A slight rise in temperature, remittent or intermittent, however, commonly accompanies the formation of tubercular peri-articular abscesses. A temperature of  $100^{\circ}$  to  $101^{\circ}$  in the evening with normal morning temperature is indicative of this complication, and this, as first pointed out by König, is an important diagnostic symptom.

Contractions, lateral deviations or other abnormal positions of the articular surfaces, usually signify destruction of the articular ligaments and articular surfaces. They are thus not seen in the articular hydrops, or the lighter forms of synovial tuberculosis, while we find them in tumor albus, or the destructive forms of para-arthritis. König very properly uses the term "destructions-contractur" (contraction by destruction), for these displacements, in preference to the usual term of spontaneous dislocations, and employs the latter expression to signify the condition when through muscular contraction or a slight injury to the joint, whose strengthening ligaments are destroyed, a sudden, very painful and often con-

siderable displacement takes place. This is especially common in the hip-joint. The clinical importance of any of these displacements lies in the fact that they signify a certain amount of destruction of the joint, thus often indicating surgical interference.

Pain as a symptom accompanying tuberculosis of the joint, although always present, is of extremely variable intensity: two patients with an apparently similar degree or form of tuberculosis in the knee-joint may differ so much as far as pain is concerned that the one may be able to walk almost without pain, while in the other, the slightest movement will cause intense suffering. Although the intensity of the pain does not give any absolutely certain information as to the extent of destruction of the joint, it may be said that in general, the more acute destructive forms of tuberculosis are the more painful, and further, that intense pain on movement may mean large intra-articular osteal foci, and extensive intra-articular destruction; while slight pain would indicate that the articular cartilage was as yet comparatively intact. A sudden attack of intense pain sometimes means that perforation of an osteal focus into the yet intact joint cavity has taken place. It is of more practical importance when we find a local painful spot on the articular extremity of the bone, especially when it is outside of the usual line of the swollen and tender capsule. Inasmuch as this may indicate an osteal focus if the tender spot shows some localized softness or swelling, it is of even more significance in this direction, and indicates a local operation which may save an as yet comparatively intact joint.

3. *Cold Abscess, the Pyarthrous Tuberculosis*, is rare. Its most typical form is found in diffuse miliary tuberculosis, and a less typical form, that is, less fluid in the joint, in the soft forms of granulating tuberculosis. The onset is usually acute, often with considerable pain accompanied by fever, so as even to simulate suppurative synovitis. There is a tendency to destruction of the capsule and the early formation of large peri-articular and inter-muscular abscesses. The symptoms of general acute tuberculosis are likely to set in sooner or later.

#### DIAGNOSIS.

As a rule there is no difficulty in the diagnosis of tuberculosis of the joints when the history, course and symptoms of the disease are taken into consideration, as above stated; but, as König justly remarks, it is well to remember that an articular tuberculosis even of the large joints, is practically a local disease, and has for a long time little or no influence on the general health of the patient. Thus we may find patients apparently strong and healthy-looking suffering from articular tuberculosis.

The hydrops tuberculosis is distinguished from a "common articular hydrops," whatever that may mean, traumatic, for instance, by its persistency and tendency to relapse as soon as the joint is put to use again. Flocculi of fibrin or rice bodies indicate tuberculosis.

The tubercular fibromas might be mistaken for lipoma arborescens or gummata. The diagnosis of the latter will be cleared up by anti-specific treatment, which should always be tried in cases of doubt.

Cold abscess is distinguished from the suppurating synovitis by less pain, some swelling of the capsule, and the frequent presence of tuberculosis in other organs.

The fungous synovitis or pan-arthritis rarely causes any difficulties in diagnosis. The elastic swelling, comparatively painless abscesses or fistulous openings with fungous granulation tissue protruding are characteristic. It can be distinguished from acute multiple osteo-myelitis of the articular surfaces by its slow and comparatively painless onset, and the slight tendency to ankylosis as compared with the latter.

The caries sicca of Volkmann, or dry cicatricial atrophic tuberculosis, especially as found in the shoulder-joint, might be mistaken for a neurosis with atrophy of the muscles covering the joint. An examination *in narcosis* will reveal some loss of mobility in the tuberculosis as compared with the absolutely free mobility in neurosis. Exact measurement may reveal some shortening, that is, articular destruction in the tuberculosis.

#### PROGNOSIS.

It is almost impossible in any given case of articular tuberculosis to state the future fate of the joint, inasmuch as the course of the tuberculosis is in the highest degree atypical. König states that all forms and cases of tuberculosis of bones and joints are capable of spontaneous recovery with more or less loss of function; but it may be stated as a general rule that the softer and more acute the tuberculosis, the larger the osteal foci, the earlier the suppuration and the less careful the early treatment, the more grave is the prognosis. An apparent recovery is always uncertain as to its duration, inasmuch as relapse or rekindling of the tuberculosis is likely to take place at any time. The articular tuberculosis usually extends over many years, especially the fungous pan-arthritis. The caries sicca may, according to König, come to an end in two or three years with some loss of mobility. Lighter forms of synovial tuberculosis or articular hydrops may disappear by proper treatment in a much shorter time.

As to the question when it can be said that recovery or disappearance of the tuberculosis has taken place, we may be guided by complete disappearance of the pain and swelling, and by the

painlessness of what mobility has been left in the joint. As has been stated before, complete ankylosis is rare, but when it takes place it gives this advantage, that the pain disappears, even when the tuberculous foci are left in the capsule or the bones.

As to the prognosis in different ages, it may be said in general that children will more easily recover even from a severe articular tuberculosis than adults—a fact that permits of more extensive conservatism in the treatment of tuberculosis in early age. This is an important fact, as the articular ends, as is well known, play an important part in the growth of the extremities, and destructive operations in children are apt to leave useless limbs from lack of growth.

The danger to life from articular tuberculosis presents the following points for consideration:

1. Sepsis, a secondary invasion of the pus microbes into the joint and peri-articular abscesses, is not uncommon. The pus microbes invade, not by auto-infection, but through careless or rather non-antiseptic treatment of spontaneous or artificial openings leading to peri-articular abscesses. It may thus be said that although practically this complication is not an uncommon one, it can be prevented by careful, systematic, antiseptic treatment. The difficulty is that the fistulous openings into tuberculous joints remain open for months and years, attendants and patients grow careless in course of time, and late septic invasion takes place.

2. General tuberculosis, acute or chronic, is much more grave, since it is impossible to prevent it. In the course of years a number of patients succumb to this complication. Billroth states that in sixteen years 27 per cent. were lost in this way. König, from a table of 117 operations for tuberculosis, found that after four years 16 per cent. had died from general tuberculosis.

3. It has recently been pointed out by various authors, especially König, Wartmann, and Albrecht that operations on tuberculous joints may cause immediate infection, the so-called operation tuberculosis. This complication is not very common; König in his extensive experience has seen only sixteen cases, and Wartmann, from a collection of excisions amounting to 837 cases with 225 deaths, found only twenty-six cases of operation tuberculosis. It sets in, as König describes it, seven to ten days after an operation, which may be aseptic and heal by first intention, either as acute tuberculosis of the lungs or tubercular meningitis, terminating in death three to four weeks after the operation. Sometimes in cases where the operation is followed by suppuration and secondary operations become necessary, it follows these.

4. A number of patients in the course of years succumb to amyloid degeneration of the spleen, the liver and especially the kidneys, with

its accompanying dropsy, which takes away some of the survivors.

I shall say nothing as to the treatment of the articular tuberculosis, inasmuch as this question belongs to special surgery, and would be altogether too extensive to be taken up in the time allotted by this Society to the discussion of the question of tuberculosis.

However, before leaving the field of tuberculosis I want to call the attention of the Society to a comparatively rare localization of the tubercle bacillus, and to an affection that has only been recently recognized as such, namely,

#### TENDON TUBERCULOSIS.

Tendon tuberculosis is a necessary appendix of tuberculosis of the joints. I do not mean tuberculosis of the tendons where the tuberculosis creeps out along the tendons from a tuberculous joint, as you find it around the tendo Achillis from the ankle joint, or the flexor tendons of the arm from a tuberculous wrist-joint; but I mean primary tendon tuberculosis, which is on an equal footing with any other primary synovial tuberculosis. The subject of tendon tuberculosis is a new one. French authors more than thirty years ago called attention to a so-called fungous tendon synovitis, describing it, as far as gross appearances go, very well, but of course they did not come to an understanding about its pathology any more than about that of the so-called synovitis of the joints. Nothing was done until 1875 when Volkmann<sup>1</sup> gave a masterly description of the tendon tuberculosis, but without recognizing it as a tuberculosis. Then came Riedel, König's assistant, who showed that the rice bodies so commonly found in the so-called fibrinous hydrops of the tendon sheaths, or hygromas of the flexor tendons of the hand always indicate a synovial tuberculosis.

I wish only to say a few words about the pathology of this form of tuberculosis, because as far as it needs treatment, it is a synovial tuberculosis—a fungous synovitis. It is a tuberculosis with an enormous development of tuberculous tissue in the sheath of the tendon and on the tendon itself. In the sheath of the tendon it forms a layer of from one to four lines in thickness, of the usual well-known gelatinous tuberculous tissue. On the tendon it forms a similar layer usually smaller and with that important anatomical feature that this granulation tissue creeps down between the bundles of the tendon and separates them until finally it makes a perfect brush out of them; then atrophy of these separate bundles of the tendon takes place and the tendon ruptures—a spontaneous rupture in the same sense as a spontaneous fracture, that is, that with a very slight movement the tendon tears. If left alone this tendon tuberculosis has the same

fate as tuberculosis of the same character in other parts of the body; it goes on to liquefaction of the tubercles and the surrounding tissue, and pus, if we may so call it, tuberculous pus without the pus microbes, forms. This abscess is opened or breaks spontaneously, leaving tuberculous fistulæ with no tendency to heal, just the same as fistulæ leading into tuberculous joints. The same fate, as with all other tuberculous tissue, will be the result of the opening, namely, that if septic invasion from without takes place, that is, if the tuberculosis is not removed at that time, or anti-septic precautions taken, then sepsis sets in and finds a congenial soil in the tuberculous tissue, an excellent culture soil for the common pus microbe; just the same as in tuberculous abscess from Pott's disease, or tuberculosis of the vertebral column, in which the opening is, in the large majority of cases, the beginning of the end. Tendon tuberculosis most commonly attacks the flexor tendons of the hand; then we have the so-called hygroma of the hand with its swelling in the palm and above. These are undoubtedly always tuberculous; further we find isolated tendon tuberculosis in the extensor tendons of the hand, more rarely in the tendons of the lower extremity, as the patellar ligaments, of which I have seen one case.

I wish to present a patient to-night who has kindly consented to come down and show his hand. The history is as follows:

John Harrington, laborer, aged 35. Family history good. The present trouble commenced about three years ago when the patient noticed a slight painless swelling on the dorsum of his hand. A watery fluid collected which was removed but collected again; the increased swelling gave rise to severe pain and inability to flex the fingers. After a few months the swelling broke spontaneously, and there was a sero-purulent discharge. This discharge continued for about two years, the swelling increasing slightly, until October 27, 1888, when the patient came to my clinic at the College of Physicians and Surgeons.

Examination revealed a swelling about five inches long in the median line of the dorsum of the hand extending from about one and one-half inches from the metacarpo-phalangeal articulation to beyond the wrist-joint.

*Diagnosis:* Tendon tuberculosis of the extensor tendons of the hand. An incision was made extending from within half an inch of the metacarpo-phalangeal articulation, seven inches up the forearm in the median line, over the swelling. The incision was made down to the muscles and tendons and a quantity of rice bodies removed; these were also found inclosed in the sheaths of each of the tendons when opened. The sheaths of the extensor tendons were removed and each and every tendon was thoroughly scraped to re-

<sup>1</sup> Beiträge zur Chirurgie.

move the tuberculous material. The extensor tendon of the thumb was divided, it being impossible to separate the tuberculous tissue without this. The tendon was united to one of the other extensor tendons. The integument was sutured with silk and the hand and forearm dressed antiseptically. One week after the operation the wound had united, and the sutures were removed and the hand dressed. Two weeks after the operation there was good union. Four weeks after the operation flexion and extension of the fingers was regained. There was no sign of return of the disease.

When this man came for operation, one of the tendons, the short extensor of the thumb, was destroyed; the others could be separated from the tuberculous tissue. This dissection of the tendons from the tuberculous tissue takes a long time. It has to be done with the utmost care because the tuberculous tissue that runs down between the fibres of the tendons is adherent; there is no short way of rubbing it off the tendons, it must be dissected off carefully, particle by particle, and then the whole sheath of the tendon dissected off with scissors and forceps, just as carefully as in the joints, particle by particle, and this law holds good in all operations for tuberculosis. Then come the difficulties of dressing. It has been found that in dressing with drainage tubes, antiseptic washes, etc., the results are not as good as if the wound is left to heal by the organization of an aseptic clot, as Lister called it. But this healing without drainage implies that the wound shall be filled with blood. No exact union of the wound is made, but a couple of spaces are left between the sutures so that the surface blood can get out. Schede recommends this method, having found that the connective tissue formed in the nidus of the clot was more pliant than the connective tissue formed when there was drainage. That method was used in this case, and the consequence is that much more extension than before is possible. This patient also shows a tuberculosis of a metacarpo-phalangeal joint.

The prognosis as to the future functions of the tendons depends upon perfect asepsis (if there is not perfect asepsis then the result is lost); supuration must not take place after the operation. It further makes a great difference as to the future function of the hand whether the tuberculosis is on the dorsal or on the palmar side. On the palmar side of the hand where we have to open from the palm up to the middle of the forearm, the palmar ligament may be divided and re-united with sutures, and it may be necessary to do this so as to dissect out the wall of the common tendon sheath. Tuberculosis in the palm of the hand gives much less satisfactory results after operation for removal of the tuberculous sheath from the tendon, than on the dorsal side

of the hand. Another point is that when the tuberculosis has reached the upper end of the tendons it creeps up the muscles not only in the loose connective tissue, but up between the bundles of the muscular fibers. This we can recognize with the naked eye by the color and consistency of the muscle. The invaded muscle becomes hard and grayish and is not shining as the normal muscle tissue. Of course all this tissue has to be cut away carefully, because it is one of the modern improvements of our technique in operating for tuberculosis that every part of the diseased tissue is carefully removed from the joints by scissors and forceps, so as to leave, if possible, no tuberculous tissue at all. This makes a very different operation from the one where the bones are sawed off from the joints, for instance, and the abscess drained, no care being taken either of the walls of the abscess or the cartilage, the consequence being that the tuberculosis very often grows right out again and there is greater liability to sepsis setting in. These operations are long and tedious, but if perfect asepsis is secured we may expect the results to be locally permanent. Tendon tuberculosis is a rare disease; it exists only in 1 or 2 per cent. of the cases in the statistics of tuberculosis.

## MEDICAL PROGRESS.

---

INTUSSUSCEPTION AND THE USE OF INJECTIONS.—(By W. E. FOREST, M.D., of New York.) In the *Medical Record* for August 3, is reported a case of intussusception in a child relieved by the use of sulphuretted hydrogen gas from a Bergeon apparatus. It is stated that this is the first case, as far as known, where the Bergeon apparatus has been used for this purpose in this State.

However admirable this method may be in the treatment of the condition in question, if another method can be shown to be as effective and more safe, more simple, and more scientific, the former should give way to the latter.

Without further introduction, I will suggest to Dr. Rodenhurst and the profession in general, a method that will meet the requirements mentioned.

In using injections of either gas or liquid to overcome intestinal obstruction, one ought, if possible, to know two things, namely: 1. How much force (approximately) the intestine will stand without danger of rupture. 2. How much force one is using at any moment in giving the injection.

As to the first point, a series of experiments made by me and detailed in a paper read before the New York Academy of Medicine, and published in the *Journal of Obstetrics* in 1886, would seem to show

that it is not safe to use an injection with a pressure exceeding fifteen pounds to the square inch in a case of intussusception. and this only in adults. In infants the pressure should not exceed six or eight pounds to the square inch (see *Journal of Obstetrics*.)

Now, with the Bergeon apparatus a greater pressure than the above might be used, I suppose. With the Davison syringe I have shown that a pressure of from thirty to seventy pounds to the square inch may be exerted on the intestine, and hence a very dangerous pressure.

The objection to the Bergeon apparatus, aside from the fact that one cannot measure and regulate the pressure accurately, is its cost and clumsiness as compared with the apparatus I have suggested in the article referred to.

In order to measure the pressure used in an injection, it is only necessary to remember that one atmosphere, or fifteen pounds to the square inch, supports a column of water thirty-three feet high; hence a column of water thirty-three feet high will make a pressure of fifteen pounds upon every square inch of surface at the base of the column.

Now, if this column of water be held in a rubber tube of ordinary size, after allowing for friction of the water in the tube, it will be accurate enough to say that every two feet of the column represents a pressure of one pound to the square inch; hence a rubber tube six feet long, filled with water and held vertical, will cause a pressure of three pounds to the square inch at its base; and a tube twelve feet long will exert a pressure of six pounds to the square inch at its base; and so on.

Now, apply this principle to a case of intussusception in a child, for instance. The surgeon, instead of sending to the nearest city for a consultant and a Bergeon apparatus, goes to the drug store or hardware store and gets a rubber tube twelve to twenty feet in length. Into one end is inserted a funnel; into the other a nozzle of a Davison syringe. In order that the injected fluid may be retained, a shoulder may be made on the nozzle about one inch from the end, by winding a roller-bandage around. This shoulder will retain every drop of the injection when pressed against the sphincter. Now a pitcher of warm salt-water completes the apparatus, and the father of the child is the assistant surgeon. The patient is taken into the hallway of the house, so that the requisite elevation may be gained, the child is etherized, the surgeon inserts the nozzle of the syringe and holds it in the rectum with one hand, while with the other he manipulates the walls of the child's abdomen. The assistant pours the water into the funnel and slowly raises it, mounting the stairs at the time if necessary. When the funnel has been raised twelve feet above the level of the child's body,

great care should be exercised, as the pressure is now about six pounds on every square inch of colon below the obstruction. It is seldom that a greater pressure than this will be needed to reduce a recent invagination. The pressure should be increased very slowly, as time is an important element in reducing an invagination.

If in any case the pressure mentioned above does not bring about the end aimed at, the pressure may be increased up to ten pounds to the square inch.

For further details as to the method and when to employ it, as well as for a simple and cheap method for generating gas and its use in reducing an intussusception, I must refer to the article in the *American Journal of Obstetrics* for 1886.

In that article are the histories of two cases of intussusception successfully reduced by gaseous and fluid enemata introduced from a syphon of Vichy water.

Since publishing the method for the use of a column of water, Dr. A. S. Hunter, of this city, has used the method successfully in a case of invagination in a child.—*Medical Record*.

**MEDICAL TREATMENT OF THE INTESTINES.**—In concluding an article on the subject of intestinal obstruction (*Medical Press*) Prof. H. NÖTHNAGEL says:

"I may briefly state in one sentence all the treatment I can recommend as an hospital consultant: Absolute abstinence from food; induce the peristaltic action from below; still it from above; and above all, avoid purgative medicines. Further I know of nothing to add for the guidance of others.

"As regards other methods of treatment, very little can be said, but there are one or two forms of recent origin which I cannot pass without a remark. Washing out the stomach was introduced by Kussmaul as a remedy, but past experience of this form of treatment has nothing particular to commend itself, and has been of very little use. One advantage in using it is that it is a harmless application, and there is not any danger attending its use. The clyster I can always recommend as a most effectual remedy in all forms of fecal accumulations, but it is not suitable for fecal vomiting where there are inflammatory conditions. The object of a large clyster is to break up large fecal masses, but this is to be avoided where there is a tender bowel. Electricity is another remedy which has come into recent favor, and is not without merit. When using this agent it is recommended that both poles be placed over the tender or painful part of the bowel, or one pole introduced into the bowel. The successful cases from this treatment are so few that no opinion can be vouchsafed. There are other drugs, like belladonna, nicotine, and others that might be named, but there is one regularly prescribed drug

that might be noticed. There was a time when every stoppage of the bowel must be drugged with mercury, but the greater number of the observers of this treatment have spoken very adversely of it. No doubt an individual case has arisen where success may be attributed to the drug, but these are very few, and leave us in grave doubt when it should be used at all. If the tradition of this drug tempts you to its use in any form of vomiting, I beg to consign it to your charge with care, and trust that you will carefully use your own judgment in applying the drug where the least danger exists. In concluding my observations on the medical treatment of the bowel, I felt it my duty to say that the most severe cases that we meet in our daily practice are frequently beyond the reach of our medicines, when arising from locking of the bowel, and properly belong to the region of operative surgery for their relief."—*The Canada Lancet*.

**A CASE OF ABDOMINAL GESTATION.**—DR. H. KREUTZMANN, of San Francisco, reports a case of this description with the following interesting details: The patient, æt. 37 years, had borne two children and had twice miscarried. In February, 1888, she believed herself to be again pregnant. The last menstruation was on January 20. Two months later she had a hæmorrhage from the genitals—this was regarded as a miscarriage. From that time a sero-sanguinolent discharge took place, and repeatedly during the next two months fleshy masses were removed from the vagina. In the meantime the usual signs of pregnancy were apparent, in addition to which there was acute abdominal pain. Later on fetal movements occasioned great pain. There was much vomiting. At about the period of her expected confinement she experienced excruciating pain of a bearing down character, then the pains suddenly ceased. Attempts were made to deliver the woman *per vias naturales*. From this time on the patient's condition became much worse and she sank rapidly from fever and exhaustion. The patient was first seen by the reporter November 26, at which time she was extremely feeble; pulse 120, temp. 102°; abdomen very tense and tender. An examination under anæsthesia revealed a tumor filling lower abdomen and reaching as far as the umbilicus, above which there was tympanites. The os externum was slightly dilated and the posterior cul-de-sac was filled with a hard mass. The os uteri was then dilated by instruments and the cavity uteri found empty. Corpus uteri was palpable. Extra-uterine pregnancy was diagnosed. Seven weeks after death of the fetus laparotomy was performed by Dr. Fred Hund. Upon opening the peritoneum there was an escape of fetid fluid and gas. A full grown macerated fetus was extracted. The ovisac was everywhere adherent. The posterior cul-de-sac was occupied

by the placenta, which was left *in situ*. The patient did well at first but finally died of inanition on the seventeenth day. The autopsy revealed extensive adhesions of the ovisac to the intestines. Death was due to ichoræmia. The reporter believes that in every case of extra-uterine pregnancy up to sixth month laparotomy should at once be resorted to—the same holding good in all cases, regardless of time, where the fetus is dead. Cases which have reached the sixth month, with the fetus living, and which are distinctly abdominal ones, should be operated upon at term to recover a living child. The aim should be to remove the entire ovisac and its contents at once.—*Pacific Med. Jour.*, September, 1889.

**TUBERCULOSIS OF THE SACRO-ILIAC JOINT.**—DR. LUDWIG HEKTOEN, of Chicago, gives a very complete and interesting account of such a case, together with a complete and careful analysis of the post-mortem findings. He also gives brief reports of five other recent cases of similar character, one of which is notable as being the sole authentic instance on record of a primary synovial tuberculosis of the sacro-iliac joint. Incorporating these cases with the 55 collected by Van Hook he gives the following tabulated exhibit of the locality of the abscesses in the entire group:

Extra-pelvic, 25, or 41 per cent.	Dissecting upward (pointing in gluteal region), 2 abscesses. Dissecting downward (pointing in gluteal region), 3 abscesses.	Pointing posteriorly, 20 abscesses ( <i>i. e.</i> , immediately over the joint).	
Intra - pelvic, 36, or 59 per ct.	Dissecting upward to lumbar reg'u, 5 abscesses Dissecting outw'rd and forward.	Under periosteum, 1 abscess. Under the ileo-psoas.	Without finishing exit anteriorly, 7 abscesses.
			Toward insertion of the ileo-psoas, 11 abscesses.
	Dissecting directly downward.	1. One thro' sciatic notch. 2. Inward toward the ischio-rectal fossa.	Through gluteus, 5 abscesses.
			Downward to thigh, 3 abscesses.
			Rectum, 2 abscesses.
			Perineum or anus, 2 abscesses.

—*North Am. Practitioner*, Oct., 1889.

**TO PREVENT ABORTION.**—DR. Q. C. SMITH suggests the following:

Fluid extract of ergot,  
Fluid extract of black haw,  
Tr. belladonna,  
Tr. ipecac, . . . . . āā f 3 j. ʒ.  
Sig.—A small teaspoonful, t. d., after meals.

It is said to be especially suited to the prevention of habitual abortion, caused by deranged constitutions, and is also very effective for allaying uterine irritability resulting from traumatism or external violence. Of course the bowels should be kept comfortably open regularly. Opium is not admissible in this class of cases, unless it is desired to terminate pregnancy without delay.—*Nashville Journal Med. and Surg.*

SATURDAY, OCTOBER 26, 1889.

MEDICAL SOCIETIES AND ORGANIZATIONS.

Organization and division of labor is a theme that is of practical everyday interest to all thinking men. It engages the attention of statesmen, politicians, philosophers and financiers, as well as of the laborer, artisan, manufacturer, merchant and professional worker.

In the struggle for existence and rivalry for supremacy, effective, congenial organization is the very first act for consideration. It precedes all forms of government, and antedates all corporate existence. Corporate organization keeps step in the most beautiful manner with the development paces of the scientific investigator.

Without the invention of the lamp chimney the Standard Oil Company would never have breathed the breath of life, in the form of an organization that within a score of years has built a number of colossal fortunes, and moulded the acts of powerful State Legislatures as if they were clay in the hands of the potter. One man, even with kingly authority, could not have done this, but an effective, congenial organization was equal to the occasion.

In the last century the East India Company became more powerful and wealthy than the crown of England, and it is very questionable to-day whether organized corporate power is not greater in this country than the political power. We are quite sure it would be the greatest if our form of government were any other than republican. Men of all occupations recognize the power and necessity of corporate organization, in order

to the accomplishment of any specific purpose of magnitude.

In our profession as practitioners of the healing art, whether engaged in making bedside observations, or delving in the unknown, with or without the aid of instruments of precision, that may be fitly spoken of as supplying a third hand and eye; division of labor and society organizations are an absolute necessity. The results of the labor of any one man are usually small, but as an integral part of the labors of a whole profession that has an effective organization, his value may be compared to that of the pinion wheel in a watch; without which the entire remainder is entirely valueless as a timekeeper.

Hence, the necessity and use of professional organizations, where every member will be a living factor, properly adjusted and in the place where he will fill his mission in doing the greatest possible amount of good to himself and his fellow men.

The village and city, county and State, district and National societies all have their place, and as every member of the most obscure society has his definite place in that organization, so should all organized medical societies be brought together in order to become and form one unified, composite body, complete in all its parts, and embracing within its folds every reputable member of the medical profession in this wonderland of ours.

Through the medium of a perfected system of organization, the results of all observations, thoughts and investigations, may be deftly placed in their proper niche for utilization for the common good.

For lack of necessary facilities for presentation to and through some society organization, many a valuable discovery has literally been lost, not only to the medical profession, but its benefits for an indefinite time have been withheld from the entire world.

Not infrequently the reading of an elaborate paper brings out in discussion a greater and more valuable fund of information than the author was able to obtain through weeks of labor in scanning all the books and journals at his command.

The frictions of all society meetings have their beneficial effects. The conscious or unconscious *cgo* that is apt to be a part of every educated man, is often rasped, filed, sandpapered and finally rubbed down to a polish that is always more

becoming to an accomplished and well-bred physician, than the rough jewel he was before the process was undertaken.

With a marvelous growth of population, medical science has kept abreast of the times. Rapid transit by means of steam and electric motors; cheap and practically instantaneous intercommunication have absolutely revolutionized commercial methods of business, and singularly enough they have in like manner influenced the ways of the medical practitioner. He is summoned by telephone or telegraph and often imparts the most important and vital directions through the same instrumentality.

The physician of the period has ceased taking and looking to a cumbrous quarterly or half yearly medical magazine for his current literature, and nothing short of a weekly meets his arbitrary and hungry demands, while the doctor who has prepared a paper for publication and does not want it printed and sent on its mission within a week, is a rare man; his family are suffering from a mortality that will only remind us of those saddest words of tongue or pen—"what might have been."

The local medical society is a most important factor in our professional organization. Every such society fitly represents a cog in the great driving wheel of progress.

Noting the scientific value of society organization and the incalculable benefits to be derived from the accumulated wisdom unfolded and unbidden at the meetings, we are not to forget that one of the great benefits conferred, is the opportunity furnished by the occasion for a cultivation of peace, amity and goodwill. The people and practitioners alike are benefited in promoting inclinations for consultations, and in this manner demonstrate to the world the brotherhood of man as exemplified in our profession, and the cosmopolitan character of our art.

Professional activity has already accomplished a world of good in organizing and fostering the growth of medical societies, and now there is no more important question open for discussion than the comprehensive one as to what are the best methods to be used, in order to bring about a complete unification of the entire medical profession in their society organizations. In a recent issue of *THE JOURNAL*, we endeavored to indicate a feasible plan for bringing about a unification of

the entire medical profession of this country, through the organization and incorporation of district and other kindred societies as actual branches of the American Medical Association.

The comments directly received and borne to us have been of a favorable and gratifying character. It is our desire that the subject, which we regard as a very vital one to the Association itself, as well as to the entire medical profession, shall have the widest possible attention and discussion.

Organization means power and influence. The more thorough and complete it is made, within the most liberal bounds, correspondingly will the power and influence be great for the welfare of science, the entire membership of our profession, and that of the people.

---

#### THE HOME TREATMENT OF CONSUMPTIVES.

Sad indeed is the outlook for the consumptive who is unable to seek a change of climate when that of his home is not suited to life out of doors. So uncertain are all means directed to the local treatment of pulmonary tuberculosis, even Weigert's hot air inhalations, that the greatest hope of arresting the disease lies still in its proper climatic management. By far the largest number of consumptives, however, is compelled to forego this chance of recovery and rely upon the physician and nurse. In only too many instances the former falls into a dreary routine born of hopelessness, while the nurse is but too often an ignorant, inexperienced, though loving member of the family. This is deplorable. If for good and sufficient reasons the doctor does not resort to expensive local measures, but is satisfied if he can merely ameliorate the patient's condition and prolong life, he should at least manage the case intelligently and conscientiously. It is safe, probably, to assert that the average practitioner employs means to mitigate symptoms which in the end defeat the object aimed at. For example take the cough. This is often most harassing and the cause of the sufferer's chief complaint. What is usually given to relieve it? A cough mixture, generally a cough syrup containing opium or one of its alkaloids. The cough is mitigated, but at the expense of the stomach. The best and safest measure addressed to the relief of the cough of phthisis in its later stages

consists in the use of respirators charged with volatile substances. R. DOUGLAS POWELL states it forcibly when he says: "The effect of such inhalations is to relieve cough and to lessen expectoration, and there can be no doubt that, as I believe to be the opinion of Dr. Coghill, who has so ably advocated their use, one of their chief functions is to do away with cough mixtures; for certainly the cough linctus treatment of this eliminative period of phthisis, by lulling cough and deranging the stomach, is the very worst that could be devised." In the early stages, when inflammation is active, JACCOUD insists on the benefit to cough to be derived from persistent counter-irritation over the affected parts. At all events it should be a rule to avoid the administration of opiates except, it may be, in cases of suffering from laryngeal complications.

Another routine prescription is that of atropine for night sweats. This is all right when they are exhausting and cannot be controlled by simpler or more agreeable means; but it so often produces so much sleeplessness and restlessness, and the sweating is so often less than is represented, that a little thought on the part of the doctor will discover some efficient and more desirable remedy.

How now is it with the nursing of the consumptive? Alas! In most cases, the attention bestowed by mother or sister is fraught with such a degree of solicitude as defeats its own ends. More intelligent nursing and firm enforcement of salutary orders, with less enervating *coddling*, would be far better for the invalid.

The principle of treatment of all consumptives should be, the least medicine possible and the greatest possible nourishment. Both physician and nurse should comprehend this and work together for its accomplishment. The consumptive's stomach is sensitive already and loathes the very thought of *ingesta* of any kind. Then why increase it by drugs and particularly opium?

The wisest treatment of the phthical sufferer is to be found in his simplest and most natural management. The physician should bestow his thought upon the most suitable kinds of nourishment, modifying these as the state of the case varies. He must not content himself with issuing the vague instruction to give anything the patient can eat. Thought is necessary. At first

force upon the system all the nitrogenous food it can be made to assimilate by help of fresh air and judicious exercise. But when hectic is consuming the frame and the supply of oxygen is small by reason of extensive structural loss as well as inability to exercise, then to overload the system with such food is but to heap fuel on the flames. At such a time a readily oxidizable non-nitrogenous dietary is indicated. While the physician is thus thoughtfully superintending the character of the food, the nurse should be studying how to successfully tempt the capricious invalid to take the nourishment. In the skilful preparation and dainty serving of the viands there is ample room for the nurse's ingenuity. In all other matters pertaining to the *art* of nursing, in short in the hygiene both of the patient's person and surroundings, intelligence even more than affectionate solicitude will minister to the comfort and prolong the life of the consumptive.

Meantime the welfare of the home circle should not be sacrificed to the care of the invalid. Strict antiseptic and prophylactic measures should be carried out. The health of the well members of the family is of no less importance than the care of the sick!

It is beyond the scope of this article to detail the proper management of consumption, its aim is only to emphasize the fact that, although medical skill has not yet found a means of successfully coping with consumption, much can nevertheless be done by a wise, not by a routine, direction of the home-treatment of phthical patients.

---

#### EDITORIAL NOTES.

##### HOME.

THE TRI-STATE MEDICAL SOCIETY.—The meeting for the organization of this Society, was held at Chattanooga, Tenn., on the 15th inst., and was in session for two days. A special correspondent says that in every particular it was a complete success, and promises to embrace the best working body of medical men in the South. The membership numbers over eighty. The papers were abundant and of good quality, and the discussions far above the average in ability and interest. All in all, the outlook for the new Society is most promising. We shall have occasion to refer to its proceedings in a later issue.

WABASH SURGICAL ASSOCIATION.—The annual meeting of this Association will be held at Toledo, O., on the first Tuesday in November.

MANAGEMENT OF GARBAGE IN LARGE CITIES.—Dr. Oscar C. De Wolf, ex-Health officer of Chicago, contributes an excellent article on this subject in the *Sanitary News* of October 12. He says that thirty-five years ago preventive medicine consisted in trying to keep out disease by quarantine methods; now it consists chiefly in removing the conditions favorable to its existence and spread. The country is constantly pouring into the city the organic matter necessary to sustain the city's life. From the prairies of the West, from the fields and gardens of the South, from foreign lands, and from the seas loaded trains and freighted ships are constantly arriving and discharging the provision for the organic wants of the population. This provision is not all consumed, but a large residue remains, effete, putrefiable, dangerous, which, if not speedily cast out beyond the borders, or otherwise properly disposed of, is sure to produce a poison by its decomposition which not only directly affects the health of the community, but indirectly supplies a breeding place for the specific germs of disease and stimulates them to great activity of development.

In the country vegetable growth makes use of this effete matter as a stimulant to other growth, reorganizing it into other nutritious substances. In the city this source of putrefication is wanting; small accumulations from each family result finally in immense quantities from many families, which impregnate the soil, vitiate the air, and cling in putrid films to the walls of dwellings and to all exposed surfaces. Unless, therefore, a city is provided with the proper means to care for this refuse in a sanitary manner, the accumulation will work a steady and sure vitiation of all the avenues of life; and one of the great advances of sanitary science in the later years, along the lines of disease prevention, has been the successful effort to remove this filth from all its hiding places in alley and street, area and corner, and the indispensable provision to care for it and dispose of it by sanitary methods.

The custom of using garbage for filling low lots and old water courses within the limits of a city—and which were to be used as sites for

dwellings—or feeding it to swine, was long continued, and is even now permitted in some localities, although such methods can receive nothing but the most emphatic condemnation from sanitarians. . . .

Rats are the peculiar vermin which swarm about kitchen garbage in all our cities, and if a man may harbor 100,000,000 of these trichinæ parasites—as Cobbold says he may—then a rat may possibly be infected with 1,000,000, which at a certain period of evolution of the parasite are lying free in the intestines of the rodent, and which may be freely discharged from the bowels with the *feces*. Is it strange, therefore, that hogs fed on city garbage are peculiarly liable to this dangerous infection, and are regarded with suspicion by sanitarians as food for man when thus fed?

The feeding of garbage to milch cows is also very objectionable from the sanitary stand-point. It diminishes the vigor of the animal and vitiates the secretion of milk.

THE MEDICAL MIRROR is the title of a new journal to appear in January, under the editorship and management of Dr. I. N. Love, of St. Louis.

#### FOREIGN.

AN ANGLO-AMERICAN MEDICAL ASSOCIATION IN GERMANY.—Some English and American physicians have resolved to found in Vienna a society to be called the Anglo-American Vienna Medical Association, with a view to giving information and moral support to the English and American doctors and students of medicine who come to the Vienna University. As a rule, there are but few students of medicine from England and America, but a great number of doctors of medicine. In the last half year 103 American doctors were on the books.

A HOSPITAL FOR STUDENTS.—The Association for the care of sick students in Vienna is about to purchase, at a cost of \$22,000, a building suitable for a hospital, in which forty patients can be cared for. The annual cost of supporting the hospital is estimated at \$6,000.

DR. PROTIEROE SMITH, the founder of the Hospital for Women, Soho Square, London, died September 28, aged 80 years.

PROF. BARDELEBEN has been elected Dean of the Medical Faculty of the University of Berlin.

## TOPICS OF THE WEEK.

### LAPAROTOMY DURING MENSTRUATION.

We quote the following paragraph from the President's address, delivered at the fourteenth annual meeting of the American Gynecological Society, held in Boston, September, 1889, by DR. H. P. C. WILSON, of Baltimore:

But, gentlemen, before closing this address, which you have required me to deliver, and which is more trying to me than many laparotomies, I must present you with one question: Shall we perform laparotomy immediately preceding or during menstruation?

This is a question which frequently embarrassed me in my earlier professional experience. Books were searched and authorities consulted for its elucidation, but I found nothing to enlighten me on the subject. The medical friends with whom I consulted advised against such a procedure. In addition to this came the paper of Dr. Horatio R. Storer, read at the first meeting of this Society, in 1876, in which he concluded "that for pelvic operations, all things being equal, it is better to select the week immediately following the cessation of the catamenia" for all such operations.

Operations per vaginam may require the selection of the uterine ebb, where such choice can be made, as the dressings and attention necessary afterward may be embarrassed by menstruation; but for laparotomies involving the pelvic organs my experience teaches me to select the uterine flood, rather than the uterine ebb. During the uterine flood the circulation and innervation are in a state of tonic excitement. During the uterine ebb they are in a state of relaxation and depression; and patients thus are more liable to passive hæmorrhages, the absorption of septic poison, the deadly influence of shock, than when the system is under the stimulus of the uterine flood.

It may be said that inflammatory troubles are more apt to be set up during the uterine flood. I would ask the Fellows how many of their laparotomies have been lost by inflammation other than septic. I cannot recall one in my own experience. Shock, hæmorrhage and blood-poison have been the causes of death in all cases, and blood-poison oftener than all other causes together. —*Boston Medical and Surgical Journal.*

### PÆDIATRICS AND PUBLIC HYGIENE.

At the recent meeting of the American Pædiatric Society, the President, DR. A. JACOB, in his annual address, makes reference to this important subject as follows:

"The most vital questions of public hygiene are most intimately connected with pædiatrics. It is mainly two subjects that attract the attention of those who take an interest in children. I allude to the school and to constitutional diseases. My remarks to-day can be but fragmentary, but still I must not, both in the interest of our science and human society, omit to emphasize the fact that it still appears that our schools were establishments organized to produce nearsightedness, scoliosis, anæmia,

and both physical and intellectual exhaustion. Contrary to the treatment a colt receives at the hands of its owner, human society, or the State, permits or directs that the powers of a child should be rendered unfit for its future functions, physical, mental and moral, for these three are indelibly interwoven. It requires physical and mental education to fertilize the soil for the evolution of morals. Thus the physician, and especially he who makes pædiatrics his special study, is a pedagogue by profession. The question of school-house building and school-room furniture, the structure of bench and table, the paper and the type in the books, the number of school hours for the average child and the individual pupil, the number and length of recesses, the hours and duration of intervening meals, the alternation of mental and physical training, the age at which the average and the individual child should be first sent, have been too long decided by school boards consisting of coal merchants, carpenters, cheap printers, and under-taught and over-aged school mistresses; not, however, of physicians. The health and vigor of the American child in early years seem, according to Bowditch, superior to those of the European; why is the youth and maiden, particularly the latter, so inferior? Why is it that anæmia and neuroses eat the marrow of the land and undermine the future of the country by degenerating both the workers and the thinkers of the community, and the future mothers? If there is a country in the world with a great destiny and a grave responsibility, it is ours. Its self-assumed destiny is to raise humanitarian and social development to a higher plane by amalgamating, humanizing and civilizing the scum of all the inferior races and nationalities which are congregating under the folds of our flag. Unless the education and the care of the young is carried on according to the principles of a sound and scientific physical and mental hygiene, neither the aim of our political institutions will ever be reached, nor the United States fulfil its true manifest destiny. That destiny is not so much the political one of excluding Europeans from our continent, North or South—for indeed the participation of European civilization in the gradual work of removing barbarism ought to be very welcome—but of raising the standard of physical and mental health to possible perfection, and thereby contributing to the welfare and happiness of the people."

### THE ARTIFICIAL FEEDING OF INFANTS.

At the first annual meeting of the American Pædiatric Society, held in Washington, D. C., September 20 and 21, 1889, DR. A. V. MEIGS, of Philadelphia, read a paper upon this subject, a report of which we copy from *The Medical Record*:

The author said that, after a long experience, he had seen no reason for making any radical change in the artificial food which he had previously recommended. He had found that mother's milk never contained more than 1 per cent. of casein. This food was based upon the dilution of cow's milk, for the reason that it contains too much casein; the further need of the addition of cream because, in diluting, the fat was reduced to too small an

amount; the addition of sugar, to make it equal to the amount contained in human milk; and of lime-water, to change it from being an acid to an alkaline fluid. However, he had fallen upon several improvements to render it easier to get together the required amounts of the different constituents, and thus simplifying the work of the nurses. He directs that instead of taking cream and milk in the proportion, respectively, of two and one in eight, three parts of a weak cream be used, which is obtained as follows: One quart of good ordinary milk is obtained and placed in a high vessel, and allowed to stand in a cool place for three hours. Then one pint is poured slowly from this, care being taken that the vessel is not agitated, the object being to obtain the upper layer of fluid, rich in fat, and leave the lower comparatively poor portion behind. When the child is to be fed, there is taken of this weak cream 3 tablespoonfuls, of lime-water 2 tablespoonfuls, and of sugar-water 3 tablespoonfuls. The sugar-water is to be made in the proportion of 18 drachms of milk-sugar to 1 pint of water. This is an improvement upon the food recommended previously by the author, because it is more economical (cream being expensive) and the food is less likely to ferment.

#### THE TREATMENT OF GASTRIC DIGESTION.

In cases where there is reason to believe that gastric digestion is imperfect, common salt should be used in increased amount in the food, so that the quantity of hydrochloric acid may be increased. If, however, there is reason to believe that lactic acid is present in too small a quantity to split up this salt, then hydrochloric acid must itself be used, and where it is employed given freely in order not only to act thoroughly itself, but also to perform an equally important function, namely, the conversion of pepsinogen into the active body pepsin. In other words, deficiency of pepsin in the juice is to be corrected not by a prescription containing much pepsin and little acid, but rather the reverse, for the pepsin in the prescription is after all an extraneous product, while the pepsin brought into being by the acid is a normal secretion. Of course the quantity of pepsin must depend on a normal formation of pepsinogen, but it should not be forgotten, on the other hand, that as pepsin acts by catalysis, and is a most powerful ferment, only very small quantities of it are absolutely necessary, while large amounts of hydrochloric acid, comparatively speaking, are essential.

In an article recently published in the *Revue Médicale de la Suisse Romande* Bourget has enunciated some thoughts which are so completely in accord with the views here expressed as to be worthy of quotation. He believes, as does the writer, that the hydrochloric acid is generally the secretion which is lacking in amount, and recommends its free employment as the most important part of the treatment of gastric indigestion. He does not seem to do this because he believes it to increase the pepsin, but only because he thinks the acid secretion is more apt to be deranged than is that of the ferment. According to my own practical experience and the much more reliable information gained by experimental research, it is to be concluded, therefore, that pepsin is to

occupy the least prominent position in a prescription for gastric disturbance, and that the acid is to be freely used. Indeed, I am so surely convinced of the importance of the acid in its double sphere that I fear I am sometimes inclined to give almost no pepsin at all.—*Med. Analectic.—Mass. Med. Journal.*

#### THE MEDICAL PROFESSION AND THE WORLD'S FAIR.

Under the above caption the *Medical Record* deplors the fact that the Mayor of New York has not as yet placed a representation of the profession on the World's Fair Committee. It is not so in Chicago, where there is a regular organization of the profession working with the general committee to raise \$10,000,000 towards securing the World's Fair for this new Metropolis of the United States. The editor very sensibly remarks that "as the purposes of the Fair have so far been outlined, there will surely be a field for medical and surgical displays of various kinds. There should be historical exhibits to show the progress in the care of the sick, and in their surgical and medical treatment, with displays illustrating the old hospitals and the new, the old surgical instruments and mechanical appliances and the new. There should be illustrations also of the development of the specialties, with displays of all new apparatus and instruments of precision in every field. The development of bacteriology, the improvements in methods of teaching, historical accounts of medical progress, and of the growth of sanitary science, all would have a fitting place. It is easy to see that a medical and surgical exhibit might be made which would have great intrinsic interest, and would be of immense educational value, not only to the medical profession, but to the laity."

We would add to this a suggestion that whichever city is selected there should be held the meetings of the American Medical Association, and the various National Societies of Specialists in 1892. This is not only desirable from the standpoint of economy, but will ensure a larger attendance at the meetings, and enable the members to "take in" the medical and surgical exhibit so ably advocated by the *Medical Record*.

#### A DOG WITHOUT A BRAIN.

At the last meeting of German neurologists, held in Baden-Baden, PROF. GOLTZ, of Strasburg, reported a most remarkable experiment. He cut out, in two operations, almost the entire cerebrum of a dog, leaving only the cerebellum and a small portion of the base of the cerebrum. The animal lived for fifty-one days after the last operation and then died of pneumonia. The remarkable part of the experiment was the influence it had on the dog, who, a few hours after the operation, raised himself on his hind legs, put his paws over the side of his box, and looked inquiringly around. He could walk, eat, and drink, and would chew any food that was placed in his mouth. Waking and sleeping alternated naturally. He was restless before feeding, but afterward would become quiet and sleep. A slight touch would awaken him from sleep. During urination and defecation the animal assumed the normal position. Hearing, taste, and smell were, of course, absent—*Wiener Medical Presse*.

## PRACTICAL NOTES.

## CURE OF FISTULA IN ANO AND HÆMORRHOIDS BY ELECTRICITY.

DR. SHOTWELL, of Grand Rapids, Mich., claims complete success from the following methods of treatment: In fistula he first passes a probe with an eye point from the external opening into the rectum. He then introduces a lance-pointed probe (having likewise an eye near the end), making the point of insertion about three-eighths of an inch further from the anus, and pushes it in through the solid structures, parallel with the fistulous track, till its eye is seen within the rectum. The eyes of both probes are then threaded with the ends of a No. 24 platinum wire about 10 inches in length, and both probes are withdrawn, leaving the wire in the form of a loop. The ends of the loop are now attached to a battery, an electrolytic current turned on and the loop drawn through the partition, in its passage destroying the membrane lining the fistula. No dressing is necessary, but the bowels should not be permitted to move for one week. Union takes place by first intention. The Shotwell rectoscope is employed and the patient requires to be anæsthetized during the operation. Hæmorrhoidal tumors are similarly removed and without the occurrence of hæmorrhage.—*New Orleans Med. and Surg. Journal*.

## HYPODERMIC USE OF MORPHIA—THE INITIAL DOSE.

Great diversity of opinion exists as to what constitutes a safe initial dose in a person unaccustomed to its use. This should not exceed for an adult female one-eighth grain, for an adult male one-sixth grain. I have myself seen death follow upon the injection of one-quarter grain in an adult male, and Ringer says "a larger quantity than one-sixth grain sometimes produces serious consequences." There are, I think, two reasons for the large quantities given: (1) The maximum officinal dose of half a grain is much too high. This is evident when we consider that the maximum hypodermic dose, and that for administration by the mouth, is fixed at the same quantity, namely half a grain. All authorities are, I believe, agreed that morphia injected hypodermically is at least twice as potent as morphia given by the mouth. The maximum hypodermic dose ought, therefore, to have been fixed at one-quarter grain instead of half a grain, and we have, I am afraid, the British Pharmacopœia to thank for many fatal results that have occurred. (2) Many of the younger members of the profession have taken their standard of an ordinary dose from the quantities they were ordered, when clerks or dressers, to inject during the time they

were in the hospital. They forget that the majority of these patients were suffering from incurable disease.—*Braithwaite's Retrospect*.—*Medical Age*.

## MALE FERN AND CALOMEL FOR TAPE-WORM.

In the treatment of tænia Dr. Duchesne strongly recommends male fern combined with calomel, according to the following formula:

Eth. extract male fern . . . . . 2 drachms.

Calomel . . . . . 12 grains.

M. Make 16 capsules, which are given two at a time every ten minutes until all are taken.

The great advantage of this preparation is that the patient has nothing to drink, and that the purgative is taken along with the worm-medicine. For some people, especially women, capsules are difficult to take, in which case the medicine is perhaps best taken with molasses. Sometimes the capsules provoke colicky pains, but these can be avoided by taking 20 grs. of antipyrin fifteen minutes before the capsules. With these capsules Duchesne has yet to experience his first failure, and he has already used them in hundreds of cases. Male fern is the only remedy that will successfully expel the bothriocephalus. The treatment of tænia in children is a difficult matter, but he has been regularly successful with the following plan: After fasting twelve hours, administer the following preparation to a child of 5 years:

Eth. extract of male fern . . . . . 1 drachm.

Calomel . . . . . 6 grains.

Sugar . . . . . 2 drachms.

Gelatin, q. s. to make a jelly of ordinary consistence

The patient should be told to take an injection of salt water when the worm appears at the anus, and then sit over a vessel of warm water to float the worm and prevent it breaking from its own weight. The one point always to be remembered, on which success depends, whatever the vermifuge used, is the necessity of administering the purgative soon after the substance which stupefies the worm.—*The Weekly Medical Review*.—*Medical Record*.

## OBSERVATIONS ON THE USE OF GLYCERINE ENEMATA IN CHILDREN.

During a period of four months glycerine enemata were used at the Evelina Hospital for the treatment of constipation, to the exclusion of purgatives. The children were not allowed to pass more than two days without an action of the bowels. A carefully prepared table is submitted, showing the result of 214 injections in sixty-three children. One drachm of glycerine was given in 156 cases, one drachm and a half in forty-eight, and two drachms or more in but nine.

In 154 instances the injection was followed by normal motions, in twenty-six they were loose, and in twenty-four of more than normal con-

sistency or composed of scybala. In ten only did the enema fail to act. In no instance were there unpleasant symptoms, either local or constitutional. No child was found whose bowels failed to respond to the glycerine stimulation at one time or another.

As regards the time of action, ninety-five injections were followed by motions within five minutes, ninety within thirteen minutes, while with the remainder the time varied from thirty-five minutes to eleven hours. The failures or cases of delayed action were in tubercular patients or those who had undergone operation and were therefore restrained from exercise or movement.

After a brief summary of the action of various cathartics in common use among children, the author expresses himself as very favorably impressed with glycerine enemata, which are easy of application, unattended by pain, quick and natural in action, and followed by but few failures.—*Epitome*.—*Mass. Med. Journal*.

#### FOR CHAPPED NIPPLES.

Says the *St. Louis Medical and Surgical Journal*: MITROPOLSKY, of Moscow, recommends chloral as an excellent local means for fissured and excoriated nipples. The latter should be kept covered with compresses (soft linen soaked in a solution of  $\frac{1}{2}$  drachm of chloral in 3 ozs. of water). The compresses should be changed every two and a half or three hours. When a prolonged application is necessary, it is advisable to use a weaker lotion ( $\frac{1}{2}$  drachm to 6 ozs.) The solution leaves a thin, whitish, firmly adherent film over the diseased surface, which does not disappear by suckling. Pain and tenderness are said to be strikingly relieved almost immediately, the lesions rapidly healing. The chloral compresses do not produce any bad effects on nurslings.—*The Canada Lancet*.

#### THE MULTIPLICATION OF BACTERIA.

As regards the reproduction of the bacteria, many of them can double their numbers every hour when placed in the best conditions for their activity. In such circumstances then, a single bacterium would in twenty-four hours produce no less than 16,777,220. At the end of forty-eight hours the offspring would amount to 281,500,000,000, and would fill a half pint measure—all produced in two days from a single germ measuring  $\frac{1}{150,000}$  of an inch. Fortunately, however, bacteria can rarely so propagate themselves, they meet with all sorts of drawbacks, and thus in spite of their enormous fertility the survivors are in a general way only enough to keep up a fair balance in nature. The diseases producing bacteria, however, have no claim upon our forbearance, and in these the enormous fecundity we

cannot too closely contemplate. Some, like the bacteria of tuberculosis and glanders, propagate themselves slowly; but the great majority of the bacteria causing animal plagues will, in favorable cases, double their numbers hourly.—PROF. LAW, in *The Pharmaceutical Era*.

#### PHENACETINE IN WHOOPING-COUGH.

DR. HEIMANN, of London, writing in the *Münchener Med. Wochenschrift*, states that he was induced to try the effect of phenacetine in whooping-cough, as he had been very much disappointed with antipyrin. Although he has given children of 3 and 4 years old a few doses of 15 grains each of phenacetine, he has never found any ill effects from its use, and the results, he says, have been uniformly satisfactory.—*London Lancet*.

#### A VEHICLE FOR IODIDE OF POTASSIUM.

Milk as a vehicle for iodide of potassium completely masks the taste, and does not apparently interfere with the therapeutic qualities. Patients who could not tolerate 10 grains when administered in water could soon take 40 grains in milk with no symptoms of nausea.—*Cincinnati Lancet-Clinic*.

#### THEINE IN NEURALGIA.

PROF. J. K. BANDY, of St. Louis, finds in the hypodermic injection of theine a specific for some forms of neuralgia. The dose is from  $\frac{1}{4}$  to  $\frac{1}{2}$  gr.; the point of the needle should be brought in as close contact with the sheath of the affected nerve as possible.

#### EXPLOSIVE MEDICAMENTS.

PROF. ROBERT calls attention to the following explosive mixtures: Chlorate of potash mixed with charcoal dentifrice powder may explode, even in the mouth. Chlorate of potash mixed with catechu, or with tannin, explodes with friction, even if glycerin is added. Chlorate of potash and phosphate of sodium explodes while mixing the powder. One part of chromic acid mixed with two parts of glycerin explodes immediately. Iodine and ammonium should never be mixed together, as it is extremely apt to explode. Bromine and alcohol, forming the bromide of ethyl, often explodes. Picric acid reduced to powder explodes, when mixed with any other substance.—*Gazette de Gynécologie*.—*The Times and Register*.

#### PRESERVE YOUR INSTRUMENTS.

You can preserve your instruments from rusting by immersing them in a solution of carbonate of potash for a few minutes. They will not rust for years, even when exposed to a damp atmosphere.

## SOCIETY PROCEEDINGS.

## American Orthopedic Association.

*Proceedings of the Third Annual Meeting, held in Boston, Mass., Sept. 17, 18, and 19.*

## FIRST DAY—MORNING SESSION.

The Association was called to order by the President, DR. E. H. BRADFORD, of Boston, who delivered an address of welcome.

DR. V. P. GIBNEY, of New York, read a paper on

## THE TYPHOID SPINE.

He drew attention to a group of symptoms pertaining to the spinal column, as sequelæ of this fever, and as an anatomical designation used the term *perispondylitis*, meaning an acute inflammation of the periosteum and the fibrous structures which hold the spinal column together. He reported three cases. Careful search of text-books has failed to reveal any cases of like nature. He alluded to a similar condition in which the hip was affected.

Dr. L. A. Weigel, of Rochester, N. Y., contributed a paper on *The Relation of the Thoracic and Abdominal Walls to the Spinal Column considered with Reference to the Treatment of Antero-Posterior Curvature*.

DR. DILLON BROWN, of New York, read a paper on

## PSOAS CONTRACTION AS A SYMPTOM.

He referred to the various diseases in which this condition may be found, and gave their diagnostic points, emphasizing the phenomena by means of which each disease could be excluded.

DR. A. B. JUDSON, of New York, read a paper on

## THE PREVENTION OF THE SHORT LEG OF HIP DISEASE.

He said the deformities of hip disease are caused by the patient's efforts to so place the limb that it shall be the least disturbed by, and afford him the most convenience in, his customary attitudes and movements. They are (1) abduction; (2) adduction; and (3) extreme adduction and flexion. The second position is practically by far the most important.

DR. C. C. FOSTER, of Cambridge, Mass., reported a

## CASE OF CARIES OF THE ANKLE TREATED CONSERVATIVELY.

He gave a detailed account of the case and its treatment. He showed the patient and plaster casts of the foot before and after treatment. He held that such treatment is not so quick and easy as a successful resection, but that the final result is far superior.

DR. C. L. SCUDDER, of Boston, read

## A REPORT OF CASES OF CARIES OF THE ANKLE TREATED BY EXCISION,

exhibiting patients.

He drew the following conclusions:

1. Excision is safe, and the mortality not great.
2. The convalescence and time of after-treatment are short.
3. The disease in the foot is ended; and the prognosis is sure.
4. Profuse suppuration and its consequences are avoided.
5. The likelihood of septic infection is at a minimum.
6. The partial operation of curetting is of very little value.
7. There is no mutilation of the foot.
8. Its usefulness is very great after excision.
9. The question of tubercular infection from operative influence is yet unsettled.
10. Excision of all the diseased bone should be resorted to earlier in the treatment of chronic ankle joint and tarsal disease.

DR. JOHN RIDLON, of New York, reported a CASE OF CONGENITAL DISLOCATION AT THE HIP.

The patient, a female, aged 10½ years, came under his observation Feb. 16, 1888. The right great trochanter was 2½ inches above Nélaton's line, and it required a blocking under the foot of three inches to make her stand fairly erect.

The old pattern of the Taylor extension hip splint was applied, and the leg elevated on an inclined plane. For one year the child did not leave her bed, and so relaxation of the traction was for once permitted. At the end of this time it was possible to locate the head of the femur, which was found to be displaced upwards and forwards, lying almost directly below the anterior iliac spine, and the difference in the length of the legs was found to be reduced to one-half inch. A jointed splint was applied on Feb. 1, 1889, and the patient was allowed to get up.

DRS. R. W. LOVETT and J. E. GOLDTHWAITE, of Boston, contributed a paper entitled

## ABSCESSSES IN HIP DISEASE, THEIR PREVENTION, SIGNIFICANCE AND TREATMENT.

Three hundred and twenty cases of hip disease from the Children's Hospital were analyzed with reference to the number of abscesses occurring and the effect of treatment.

In the 320 cases 75 abscesses occurred, a percentage of 23, which very small percentage is attributed to long continued treatment with the long traction splint and by fixation in bed and traction in the line of deformity whenever deformity or sensitiveness occurred. The operation is not attended with the risk of septicæmia, nor does it prevent the occurrence of tubercular meningitis or amyloid degeneration, and finally it

may be said that thorough operation is followed, in a fair proportion of all cases, by speedy and permanent closure of the abscesses.

#### SECOND DAY.

The following papers were read: *The Principles of Treatment of Hip Disease*, by Dr. N. M. Shaffer, of New York; *The Early Local Treatment of Hip Disease*, by Dr. A. J. Steele, of St. Louis; *The Operative Treatment of Hip Disease*, by Dr. DeF. Willard, of Philadelphia, and *The Immediate Disregard of Malposition of the Thigh in the Treatment of Hip Disease*, by Dr. Barton, of Buffalo.

Dr. E. G. Brackett, of Boston, read a paper entitled *An Experimental Study of Distraction of the Hip Joint*, which was followed by one on *An Analysis of Twenty-one Cases of Hip Disease Treated by the Thomas Splint* by Mr. John H. Huddleston, of Boston.

Dr. John Ridlon, of New York, read a paper on *Fixation and Traction in the Treatment of Hip Joint Disease*, followed by one on *Excision*, by Dr. R. H. Sayre, of New York, after which a general discussion ensued.

#### THIRD DAY.

Dr. G. W. Ryan, of Cincinnati, read a paper entitled *When Shall Treatment be Dispensed With in Spondylitis?* The following were also read: *A Contribution to the Study of Flat Foot*, by Dr. V. P. Gibney, of New York; *Traumatism of the Hip, Simulating Thyroid Dislocation*, by Dr. T. H. Meyers, of New York.

#### OFFICERS FOR 1890.

President, Dr. DeForest Willard, of Philadelphia; Vice-Presidents, Drs. A. J. Steele, of St. Louis, and A. B. Judson, of New York; Recording Secretary, Dr. G. W. Ryan, of Cincinnati; Corresponding Secretary, Dr. Samuel Ketch, of New York.

Next place of meeting, Philadelphia, third Tuesday in September, 1890.

#### Medical Society of the District of Columbia.

*Stated Meeting, March 20, 1889.*

THE PRESIDENT, CHARLES E. HAGNER, M.D.,  
IN THE CHAIR.

DR. J. FORD THOMPSON reported the following cases:

#### 1. EXCISION OF THE KNEE-JOINT (PATIENT EXHIBITED).

C. A. C., æt. 23, white, American, and a carpenter by trade. Was struck on the inner side of the right knee with an adze, making an incised

wound involving the knee-joint. Inflammation ensued. He was treated by another physician for some time but kept getting worse and losing flesh and strength. When I first saw him the leg was flexed at right angles, there were several suppurating sinuses and the knee felt soft and boggy. On the 11th of December, 1888, I sent him to the Garfield Memorial Hospital, where I operated on the 13th.

The flap was made on the anterior surface and dissected back; the patella was removed, the diseased ends of the bones sawed off, and the diseased soft tissues removed. During the operation a stream of antiseptic fluid was constantly flowing over the wound. The ends of the femur and tibia were fixed by nails. The knee was then dressed antiseptically, and plaster dressing.

December 21. The dressing was changed and the wound looked well. December 23. The dressing was again removed on account of a slight elevation of temperature. From this time the recovery was steady and not marked by any untoward symptom. There was no pus in this case except where the nails were introduced, and these were removed in the third and fourth week. January 28. Discharged cured. Walking on crutches. March 20. He is present and walks with a cane.

About a year ago I reported to this Society a case of erosion of the knee-joint in a little girl 10 years old, in which recovery took place in five weeks. After the operation there was not any pus except along the line of the nails. In this case it was not properly an excision, as only diseased soft tissues and ends of the bones had been removed. I have never tried to get motion after erosion, although several cases have been recently reported in which motion was secured. I could not hope for motion in my cases and I question whether it would be proper to attempt motion. The operation of erosion is an improvement over the older practice of waiting until the tissues are so much diseased that excision is necessary. Excision is especially unsatisfactory in children, since if the ends of the bones are removed the limb will not grow. In an adult this will make very little difference, but in the child one leg would grow while the other did not, so that by the time the bone was through growing the shortening will be very marked. Erosion does not interfere with the growth of the bone.

About the time of the operation on the patient presented to-night I performed it upon a colored girl for tubercular disease of the knee-joint. She did not do very well, and as there were several sinuses I opened the joint a second time and spooned out all the diseased tissue that I could find. She is now up and about, but is in a hectic condition and does not get well. I think an amputation would have been better in the beginning, and it may be necessary yet.

## 2. INCISED WOUND OF THE ABDOMEN.

S. H., male, colored, æt. 28, Arlington, Va. This man was cut about 9:30 P.M. of May 7, 1888, and was brought to Emergency Hospital in a milk wagou from Arlington, Va., a distance of six miles, arriving at 12:30 A.M. of May 8, about three hours after receipt of injury.

I saw him within an hour after admission. He had been cut with a knife in a fight, the wound made being about 2 inches in length, extending obliquely downwards and outwards to the left, beginning just below the ensiform cartilage and the lower part extending nearly through the left cartilaginous border of the epigastric region. The patient, who was pulseless from shock, had been cared for by the house physician by application of hot bottles, hypodermatic injections of ether and arom. spt. of ammonia. Over the epigastric and umbilical region there was a large mass of abdominal contents, which upon examination proved to be the entire stomach with great omentum, and all of the transverse colon, the mass being tightly constricted at the wound, as in strangulated hernia, and covered with dirt. The protrusion was carefully washed with bichloride solution 1 to 2,500, and thoroughly examined for wounds, but none being found, a blunt-pointed bistoury was insinuated beneath the protrusion and the incision enlarged downwards for an inch or more, after which the parts were reduced by taxis.

I found it very difficult to close the wound nicely at its deeper part on account of its extending into the cartilages. I brought the peritoneum together first with catgut sutures, and then closed the wound with sutures passed as deeply as was practicable. Antiseptic dressing was used.

May 8. Temp. 100°; pulse 100; resp. 20.

May 9. Temp. 102.2°; pulse 114; quite tympanitic. Coil was applied, and enema given, which produced good stool. Temp. was reduced by evening to 99.8°; pulse 98.

May 10. Temp. 100°; pulse 99.

May 13, evening. Sutures removed; pus oozed from suture wounds, and about 2 ozs. during night from wound. Milk diet and antiseptic dressing throughout. Recovery uninterrupted.

## 3. PERFORATIVE APPENDICITIS.

I was asked by Dr. J. W. Dunn to see this case at 8 P.M., February 21, 1889. There was a history of intestinal obstruction; he was very low and hiccough was incessant. I stated that it was a clear case demanding operative interference, but concluded to postpone it until next morning.

February 22d the patient was in about the same condition and I had the family advised of the extreme gravity of the case and advised immediate laparotomy. The patient was then anesthetized and an incision in the median line was made. Upon opening the peritoneum a milky fluid escaped and I thought the intestines

had been opened. The incision was then enlarged and about a quart of this fluid escaped. The pelvis cavity was filled with it. The incision was now lengthened upwards and the intestines were found to be adherent, of a blackish color, and looked gangrenous. They were gently manipulated. They were quite distended, and four punctures were made to draw off the fluids and gases; the punctures were closed with the Lembert catgut suture. In the cæcal region an abscess cavity broke and about five or six ounces of pure pus escaped. This cavity was then washed with a warm carbolized solution. At the caput coli the intestine looked healthy, but about two feet of the ileum seemed almost gangrenous, with numerous black, soft and leathery spots. In the abscess cavity a concretion like a coffee-grain was found, which I believed to be calcareous. The appendix and surrounding tissues having a gangrenous appearance, I thought it best to remove the appendix above the deeply congested part and establish an artificial anus, because I did not think the intestine could stand the pressure of the gases and contents. I also thought that if the patient survived the operation the artificial anus could be operated on successfully. He seemed to stand the operation very well, but died three hours after of shock.

I had never seen such a condition of the intestines. I did not know how the fluid got into the man's pelvis, nor its nature. It looked like the fluid injected into the rectum, but how did it get into the peritoneal and pelvic cavities? It did not pass through the abscess, as its walls were perfect. The case had been managed by one of the most capable female nurses I have ever seen, and she gave the enemata with the Davidson syringe, and not the long tube of other syringes, which is usually passed into the intestine while the operator is in ignorance where it is going. He suspected rupture in some portion of the intestine below the disease, but it could not be examined satisfactorily, and a post-mortem was not allowed to confirm the suspicion. The disease of the intestine was beyond all I had ever seen, and I do not know what caused it. In appendicitis there is no reason for the disease extending to such an extent.

If the man had had vitality enough to have survived the immediate effects of the operation, the artificial anus would have relieved the weakened bowel and he might have been cured by a subsequent operation.

I preferred the median operation because I supposed the trouble was obstruction, but it was fortunate that it was made under such a supposition, because it proved very advantageous. In appendicitis I perform the right inguinal operation. The diagnosis in such cases is very difficult and the best diagnosticians frequently fail.

I am impressed with the importance of the

early operation, and believe that it is too frequently delayed until the vitality of the patient is too much exhausted to resist the shock of laparotomy. In many cases the trouble is merely suspected and the physician waits for positive proof, which comes too late to save life. In all cases exhibiting peritoneal symptoms combined with those of obstruction the operation is imperative.

The case reported by Dr. McArdle, upon which I operated, has entirely recovered.

The history by Dr. J. W. Dunn, of this case, is briefly as follows: C. D., æt. 21 years, sent for me between 6 and 7 o'clock, on the evening of Feb. 11, 1889. I called about 8 o'clock, and elicited the following account of his illness: The day before (Sunday) had walked to Rock Creek cemetery and back again without fatigue. Upon his return had eaten a good dinner and enjoyed it. Monday morning about 10 o'clock was seized with a pain at the pit of the stomach, which was severe and lasted until he arrived home and had vomited his breakfast, which consisted of two soft boiled eggs, some bread and a saucer of preserved peaches with cream. The violent pain then disappeared. Vomited bile and mucus several times during the afternoon. Was given crushed ice and brandy, and when I arrived had not vomited for nearly two hours. Upon examination detected nothing abnormal, with the exception of a feeling of soreness over the region of the stomach. Said he was not ill but his bowels had not moved. I then ordered 1 grain of calomel in eight powders. One every two hours. Said he would send for me if he had further trouble. Temperature 98.6°; pulse 74.

Did not hear from him again until Friday, the 15th. Found him in bed, but had been up and around the house, and had eaten three meals a day. Said the soreness over the stomach had not gone away. Only felt it when erect, not when lying down. Was perfectly horizontal and free from pain. No pain on pressure over cæcum or in iliac region; thigh not flexed on pelvis; could extend leg freely and easily; no hardness; and abdomen uniformly tympanitic. Had not had nausea. Temperature 98.6° taken in the mouth; pulse 76. The calomel had not operated, and his mother had given him a dose of castor oil, which had moved the bowels three times freely. Gave sulphate of quinine 2 grains every 4 hours, and ordered turpentine stunes over bowels.

From this time until Monday the 18th, his condition remained about the same. Had two or three light colored and offensive movements daily. Abdomen tympanitic and slightly swollen. Tongue of a natural color, and white fur on posterior portion. On this date (18th), seven or eight dark red spots appeared over the lower portion of the chest, disappearing in twenty-four hours.

Highest temperature recorded 101.4°; pulse never over 96 per minute. Made diagnosis of "mild case of typhoid fever."

19th. Complained in the morning of nausea; bowels had not moved since evening before. Gave drachm doses of granulated effervescing citrate of magnesia, to be repeated every hour. This quieted the nausea, and at 9:15 P.M., produced a slight movement with quantities of offensive gas. At 10 P.M., the nurse gave an enema of one quart of warm water with soap-suds, which did not come away, and was repeated in one hour. 12:15 A.M., enema came away, bringing two hard pieces each, about three inches long. The nausea returned at this time.

20th, 2:30 A.M. Had severe pain in right side, came on suddenly and rapidly, subsided with applications of hot water and turpentine. Said the milk made him sick and vomited it with some greenish material and mucus three times during the day, viz.: at 11:45, 4:35, and 7 P.M. No movement during the day; 7 P.M., enema one quart, came away in thirty minutes, bringing four brown pieces and about two inches in length. The milk was withdrawn, and he did not vomit again. Pain in side did not return. Abdomen only moderately distended. No evidence of typhlitis or of perityphlitis. Was moderately tender on pressure on both sides. Principal soreness just below ensiform appendix. Temperature 101.2°, pulse 104.

21st, 2 A.M. Small movement, about 2 oz. of yellow fluid; 6:15 A.M., some yellow movement of about 4 oz.; 7 A.M., vomited about one pint of greenish material; after this seemed much better; 10:15, enema; slight movement with four small pieces; 4:30 P.M., vomited about 4 oz. of insipid-looking material, yellow in color. Had no marked fecal odor; 5:50 P.M., large enema (two quarts), came away hardly stained. Nurse stated that he had hicough during the afternoon; 9:15 P.M., enema of one quart of infusion senna; came away in one hour, one small yellow piece. Abdomen swelled rapidly on 21, and was much distended by 6 P.M. Enemata with exception of a few small pieces, were hardly stained. Temperature 101.8°; pulse 108.

Treatment consisted of 2 grains of quinine every four hours for three days, after which no medicine but the magnesia was given by mouth. Suppositories of morphine  $\frac{1}{4}$  grain were given occasionally to procure sleep. Hot applications over bowels constantly. Diet consisted of milk and liquid beef peptonoids.

#### 4. TWO CASES OF STRANGULATED FEMORAL HERNIA.

*Case 1.*—I was asked by Dr. Busey to see Mrs. B., who had a strangulated femoral hernia of the right side, of several days duration. I examined her on Feb. 10, 1889, and found a small tumor,

resembling a gland, just below Poupart's ligament, and I advised an immediate operation. Upon opening the sac I found a small knuckle of intestine, so very much congested that it looked at first to be in condition of gangrene; but after irrigation with warm water its appearance improved and it was returned. The sac was dissected off and tied with double catgut ligature as high up as possible in the ring. A drainage tube was inserted into the peritoneal cavity through stump of sac. Patient recovered with bad symptoms. The wound healed by granulation. The patient had no fever, and she was given an enema on the third day, which brought away feces.

I think drainage is necessary in such cases as this for the radical cure of herniæ, and I expect a radical cure in those cases in which the sac is removed. In the following case also the sac was dissected out and the wound allowed to heal by granulation.

*Case 2.*—March 1 Dr. Koonen asked me to see Mrs. G., white, aged 37, the mother of one child 14 years old. She stated that she had been ruptured about six years previously, but that it had never caused her any trouble until about three days previous, when lifting a heavy barrel she felt a sharp pain in the right inguinal region, and that she had been vomiting for the past two days. On examination Dr. Koonen found a large femoral hernia, inflamed and irreducible. March 1, the operation described above was performed. March 2, temp. 100°, pulse 96; abdomen slightly tympanitic, and pain in right iliac region. March 4, temp. 96.6°, pulse 95. Had a natural stool. March 6, discharged cured.

In these cases the strangulated knuckle of intestine was enclosed by an omental sac. After relieving constriction the intestine was returned, the omentum transected and tied with catgut ligature high up in canal, and this large mass cut away. The sac was then dissected out, tied and cut off as in previous case. Drainage tube was inserted and antiseptic dressing applied.

Recovery without bad symptoms.

The concretion removed from the case of perforative appendicitis was referred to the Committee on Microscopy.

DR. KOBER: In the after-treatment, did Dr. Thompson desire to secure bony or fibrous ankylosis?

DR. THOMPSON: The operation is not complete unless there is bony union, as in case of fracture.

THE PRESIDENT: Some time ago he had seen a case of fracture of the patella by direct violence, in which there was subsequent union. Some time afterwards this patient, in an effort to break a fall, fractured the other patella, and union took place in it, making both limbs alike. He walks very well since the second accident.

DR. KOBER simply desired to direct attention to

the different results obtained so far as the mortality was concerned, when excision was performed for traumatic causes and when performed for disease. Of 116 cases of excision of the knee-joint, collected by Gurll, there were 21 recoveries and 95 deaths, or 81.89 per cent. Whilst of 431 cases collected by Penieres, operated on for disease, 300 recovered and 131, or 30.4 per cent., died, showing a difference of 50 per cent. in favor of the cases operated on for disease.

DR. THOMPSON: Conclusions drawn from statistics of several years ago are of little surgical value nowadays. There has been such a revolution in surgery that the results now attained are far better than those for the same operations a few years ago. The case reported was traumatic, and still it got well without a bad symptom.

## FOREIGN CORRESPONDENCE.

### LETTER FROM PARIS.

(FROM OUR REGULAR CORRESPONDENT.)

*Dr. Guéniot on the Causes and Treatment of the severe or obstinate Vomiting of Pregnancy—Dr. Marc Sée on Congenital Hypertrophy of the Right Lower Extremity—Prof. Gayet on the Wearing of Celluloid Artificial Eyes—Antipyrin in the Treatment of Enuresis—The Incompatibility of certain Antiseptic Substances.*

At a recent meeting of the Academy of Medicine Dr. Guéniot read a memoir on the causes and treatment of the severe or obstinate vomiting of pregnancy. According to the author there are three principal factors concerned in the etiology of this form of vomiting, viz.: the uterus, the nervous system and the stomach, consequently it is against the alteration of one of these organs that the treatment should be directed. Thus, as regards the uterus, there may be ulceration of its neck, or a flexion of its body on the neck may be a source of irritation which reflects on the nervous system and the stomach and thus produces obstinate vomiting. On the other hand, it is possible that diseases of the ovum may cause the vomiting. The author had seen a patient who was the subject of a hydatiform pregnancy who was affected with obstinate vomiting. Some irritability of the nervous system might also reflect on the stomach. Finally, the stomach itself may be diseased, which would singularly predispose to vomiting. These etiological considerations should guide the physician in the treatment to be adopted. It is thus that in rectifying a flexion or deviation of the uterus, the raising of the hip combined with the lowering of the trunk is sometimes sufficient to arrest these persistent vomitings, and the application of a suitable pessary sometimes gives good results. If there be ulcer-

ation of the neck, topical remedies and even cauterization may be employed without fear of provoking abortion. If there is a tumor, it must be excised. If there is vaginismus, it must be combated by prolonged baths and the application of an ointment of cocaine. Even when an examination discovers no lesion on the side of the uterus, dilatation of the neck practised with the finger in multiparæ, with laminaria or a dilating instrument in primiparæ, would often arrest the vomiting. If there is irritability of the nervous system, enemata of the bromide of potassium or of chloral should be employed. The application of Chapman's ice bag to the dorso-lumbar regions of the spine, also gives good results. The ether spray to the spine and to the stomach, practiced just before meals, is often sufficient to check the vomiting. Inhalations of oxygen are also beneficial. If there be disease of the stomach, the patient must be subjected to a rigorous diet, all acidulous and alcoholic drinks must be suppressed. Ice, Vals or Vichy water, milk or beef tea to be taken often, but in small quantities at a time, may be allowed.

At the same meeting Dr. Marc Sée read a report on a case of congenital hypertrophy of the right lower extremity related by Dr. Duplony at the meeting of the 20th of August last. Dr. Marc Sée is of opinion that before practicing disarticulation of the thigh, the surgeon should try ligature of the artery, and he would strongly recommend the application of elastic compression, from which he had obtained excellent results in a similar case.

Prof. Gayet, of Lyons, reports that he had lately observed several cases in which the wearing of artificial eyes made of celluloid was attended with some inconveniences. Artificial eyes made of this substance have not the brilliancy nor the lifelike appearance of eyes made of glass or enamel, but they do not break, are easily adapted to the hollows and projections of the orbital cavity which has been modified, they are much cheaper. Patients may even, when granulations or adhesions are formed in the orbital cavity, cut the piece in such a manner that it will continue to well adapt itself to the orbital cavity. Thus it will be seen that these pieces in celluloid have certain advantages, but they have the great inconvenience of not being tolerated more than three or four months. At that time their chemical composition is probably modified by the liquids of the eyelids and of the orbital cavity, as well as by the tears which keep them constantly wet, so that the stump becomes red, granulating, painful, and gives rise to an abundant purulent secretion which compels the patient to abandon his artificial eye. Antiseptic washings may give some relief, but there remain the vegetations, which must be cauterized or excised. A cure is effected, but if the patient reapplies the artificial

eye of celluloid he soon returns for the same treatment. The author does not know where these artificial eyes are manufactured, but believes that they come from Germany. They are composed of two distinct parts. The sclerotic is of celluloid and contains at its anterior part a cavity in which is implanted a piece similar to that of eyes of glass forming the iris and the cornea. When the sclerotic becomes altered, at the end of three or four months, it sometimes acquires an odor of an extraordinary fetidity. This odor recalls that of bromine, and it is no wonder, as celluloid is made of the mono-bromide of camphor. It is therefore possible that the bromine at a certain moment is set free, and gives rise to this odor. Under the influence of the heat the sclerotic becomes altered and softened, the central piece (the iris and the cornea) becomes somewhat movable in its cavity, and there results a cutting edge on which rub the posterior surfaces of the eyelids.

Starting from the idea that enuresis is due to a spasm of the fibres which preside the expulsion of the urine, Drs. Perret and Devic treated two cases of essential nocturnal incontinence of urine, the one aged 11 years and the other 12 years, to whom he administered from 2 to 3 grams of antipyrin per day. The first case, which was that of a boy, was cured in ten days after treatment, and the second, a girl, was cured in fourteen days. Even after the suppression of antipyrin the enuresis was not reproduced.

The *Archives de Pharmacie* points out the incompatibility of the following antiseptic substances: Corrosive sublimate and iodine, corrosive sublimate and soap, carbolic acid and iodine, carbolic acid and the permanganate of potash, iodine and soap, salicylic acid and the permanganate of potash, permanganate of potash and oil, soap and glycerine.

### Snake Bites—A Correction.

*To the Editor:*—In the issue of THE JOURNAL for September 28th I notice the following item, clipped from *The Southern Practitioner*, which is calculated to make a very false impression, at least in the minds of your northern readers, and to do our section of the State of Texas great injustice:

Dr. L. G. Lincecum, of Lampasas, Texas, reports that he has treated more than one hundred cases of bites inflicted by poisonous reptiles, and that he has never seen a case result fatally that was treated by the hypodermic administration of permanganate of potassium and the administration of chloroform locally and by means of inhalation. He gives the permanganate in 1 and 2 grain doses.

I have now practiced medicine in Texas eight

years, part of the time in the northwest portion of the State known as the Panhandle, and the last five and one-half years in Lampasas. I have treated four cases of bites from poisonous reptiles. My practice and acquaintance extend over a region of from fifteen to twenty miles in either direction from town. Two of my cases were in the Panhandle, the other two in this vicinity. I am in position to know of the occurrence of snake bites in any part of the county. I have heard of but two or three cases besides my two cases.

Dr. Linccum has practiced medicine here for fourteen or fifteen years. If he has treated one case a year here it is far more than anybody here knows anything about in the practice of all the other physicians here. If he has treated "*over one hundred cases*," it certainly must have occurred before he came here—probably whilst he practiced in the city of Austin.

We do not deny but that there are venomous reptiles and insects in the State of Texas, but they are not as numerous as many are led to suppose, and bites and stings from them are of rare occurrence. There are physicians in Texas who have never seen a case of rattlesnake bite in a practice of years. Others, in certain localities, might treat two or three cases a year. There is no question in regard to the success of the permanganate of potassium treatment in these cases.

Respectfully, J. D. CARIART, M.D.,  
Member of Texas State Medical Association; of the American Medical Association; delegate to Ninth International Medical Congress.

### Erysipelas Complicating Pregnancy.

*To the Editor:*—In a paper read before the Indiana State Medical Society, June 6, 1888, on "Erysipelas Complicating Pregnancy," the following conclusions were based on an analysis of thirty-seven cases:

1. The nearer to full term the attack of erysipelas, the less danger of death and greater certainty of abortion or premature delivery.
2. That nearly all cases complicated by puerperal peritonitis die, while those not thus complicated get well.
3. That there is less danger of death to the pregnant in the later months of pregnancy suffering with erysipelas than to the parturient to whom erysipelatous virus has been conveyed, producing puerperal peritonitis.
4. That the dangers to the pregnant or parturient are greatest in the active invasive stage of erysipelas; that puerperal septicæmia is not so likely to follow those cases of abortion or premature delivery occurring in the retrogressive stage of the erysipelatous inflammation, and that the dangers grow less as the inflammation subsides, provided the system is not left in a condition favorable to a return of the erysipelas.

5. That the virus from all varieties of erysipelas should be considered dangerous to the parturient, regarding the intensity of the inflammation and time of development of the virus as greater factors for evil than the variety and situation of the erysipelas.

Seeing that my conclusions were incorrectly stated in an important publication of wide circulation, and desiring to further investigate the subject, this communication is sent for publication.

Wishing to see if a larger collection of cases will further establish the above conclusions, any of the readers of THE JOURNAL having had cases of erysipelas complicating pregnancy, are respectfully requested to report them to the writer according to the outline given below. Only cases of erysipelas occurring in the pregnant from the time of conception to commencement of labor are wanted, and not those cases of septic infection occurring after delivery.

*Form.*—1. Period of pregnancy at which erysipelas occurred. 2. Variety and situation of erysipelas. 3. Time of delivery as to stage of erysipelas and period of pregnancy. 4. Result as to death or recovery of mother. 5. Did mother have puerperal peritonitis or septicæmia?

To any one reporting cases due credit will be given, and a reprint of the article on the above subject will be sent to them if requested. Please send reports to,

Yours respectfully,  
R. R. KIME, M.D.

Petersburg, Ind., Oct. 12, 1889.

### Etiology of Tetanus.

*To the Editor:*—Recent articles and communications in THE JOURNAL on the contagion or microbe of tetanus, and its relation to the offal of animals, have added interest, in view of the occurrence of a case of tetanus which, during the week past, has in this city reached a fatal termination. The victim was a woman of advanced age, but of notably vigorous health. About two weeks previous to her death she had occasion to step into a poultry coop or enclosure, when a nail, concealed by dirt and offal of the poultry, penetrated the plantar surface of the instep. In a few days stiffness of the cervical tissues appeared, with the result stated. As many medical men in a lifetime of active practice fail to meet a case of this kind, so rare is the disease outside of hospitals, albeit rusty nail wounds of the feet are sufficiently frequent, the special circumstances of the etiology of this case are significant, as verifying the recent view of a microbe origin. The writer was not medically in the case, but is accurately informed of the above facts, and would regard their burial with the victim with disfavor.

Yours respectfully,

H. C. MARKHAM, M.D.

Independence, Ia., October 11, 1889.

## NECROLOGY.

### Dr. Charles W. Haddock.

DR. CHAS. W. HADDOCK, a well-known physician of Beverly, died Oct. 10, 1889. He was born at Hanover, N. H., sixty-seven years ago. His father was a clergyman and a professor in Dartmouth College, in which university the future physician was graduated. In 1847 he went to Beverly, where he won a high reputation. He was a member of the Massachusetts and Essex South District Medical Societies. He was surgeon of the 8th Regiment Massachusetts Infantry during its nine month's campaign in the Carolinas, and was surgeon of the 2d Corps of Cadets for several years. He had been medical examiner for the Beverly district since the office was created, and was chairman of the Board of United States Pensioner Examiners, having been recently appointed. His wife and one son, Dr. Charles W. Haddock, survive him.

## MISCELLANY.

EPIDEMIC DISEASE IN BELFAST.—At a meeting of the Belfast Dispensary Committee on October 7, the reports from the various medical officers showed the existence of a large amount of typhoid and typhus fevers in the city. The outbreak of typhoid was attributed to the heat and drought of the early summer, succeeded by the wet weather of August. There is reason for thinking that a conjunction of circumstances of this kind does tend to have this effect. Happily, the epidemic is not of a severe type, and the mortality has been very moderate. Dr. Woodhouse, Local Government Board Inspector, stated his opinion that 10 per cent. of the death-rate was due to diarrhoea in infants, of which the causes were mainly two—wrong feeding and imperfect sanitation.—*British Med. Jour.*, Oct. 12, 1889.

### *Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 12, 1889, to October 18, 1889.*

Capt. Louis Brechemin, Asst. Surgeon U. S. Army, relieved from duty at Ft. Laramie, Wyo. Ter., and ordered to Ft. Apache, Ariz. Ter. Par. 2, S. O. 241, A. G. O., October 16, 1889.  
First Lieut. Alfred E. Bradley, Asst. Surgeon U. S. Army, relieved from duty at David's Island, New York Harbor, and ordered to Ft. Omaha, Neb. Par. 2, S. O. 214, A. G. O., October 16, 1889.  
First Lieut. H. S. T. Harris, Asst. Surgeon U. S. Army, relieved from duty at San Antonio, Tex., and ordered to Ft. Keogh, Mont. Par. 2, S. O. 241, A. G. O., October 16, 1889.  
Capt. Edward Everts, Asst. Surgeon U. S. Army, relieved from duty at Ft. Apache, Ariz., and ordered to David's Island, New York Harbor. Par. 2, S. O. 241, A. G. O., October 16, 1889.  
Capt. W. R. Steinmetz, Asst. Surgeon U. S. Army, ordered for examination for promotion. Par. 3, S. O. 236, A. G. O., October 10, 1889.  
Capt. Louis Brechemin, Asst. Surgeon U. S. Army, granted leave of absence for one month. Par. 1, S. O. 98, Hdqrs. Dept. of the Platte, October 12, 1889.  
Capt. George W. Adair, Asst. Surgeon U. S. Army, leave of absence extended for fifteen days. Par. 15, S. O. 238, A. G. O., October 12, 1889.  
Capt. Valery Havard, Asst. Surgeon U. S. Army, leave of absence extended one month. Par. 3, S. O. 240, A. G. O., October 15, 1889.  
Major L. Y. Loring, Surgeon U. S. Army, sick leave of absence extended two months on surgeon's certificate of disability. Par. 16, S. O. 241, A. G. O., October 16, 1889.  
Lieut.-Col. Anthony Heger, Surgeon U. S. Army, relieved from duty in Div. of the Atlantic, and ordered for duty as attending surgeon, Washington, D. C. Par. 2, S. O. 241, A. G. O., October 16, 1889.  
Major Robert M. O'Reilly, Surgeon U. S. Army, granted leave of absence for six months, with permission to leave the United States. Par. 3, S. O. 241, A. G. O., October 16, 1889.

### *Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending October 19, 1889.*

Surgeon D. W. Bertolette, detached from the "Franklin," and ordered to duty at Naval Hospital, Philadelphia.  
P. A. Surgeon N. H. Rush, detached from Naval Hospital, Philadelphia, and ordered to the "Saratoga."  
P. A. Surgeon C. T. Hibbett, ordered to the "Franklin."

ADDRESSES.

THE ADDRESS DELIVERED BEFORE  
THE AMERICAN PUBLIC HEALTH  
ASSOCIATION,

*At Brooklyn, N. Y., Oct. 22, 1880.*

BY H. A. JOHNSON, M.D.,  
PRESIDENT

[Abstracted for THE JOURNAL]

*Gentlemen of the Association, Ladies and Gentlemen:* Article second of the Constitution of the American Public Health Association declares that the object of this Association shall be the advancement of sanitary science and the promotion of organizations, and measures for the practical application of public hygiene.

In the furtherance of this object it has seemed wise that there should be at its annual meetings not only papers upon purely scientific subjects, but that also, in the form of essays or public addresses, an effort should be made to secure the interest and coöperation of those of our citizens who have no official or professional relations to the objects of the organization. In other words, to invite the support of all classes of society in the advancement of public health.

To do this we must demonstrate the truth of the maxim of one of our greatest philosophers that "Public Health is Public Wealth." I shall not, therefore, address myself so much to the scientist, the official and professional sanitarian, as to the people, who, by their presence here to-night, give evidence of sympathy and interest in our work—or rather their work—and to whom, after all, we must look for means to carry out such measures as science shall demonstrate to be for our race most beneficent. Through the ages but little has been done to prolong life and mitigate distress. We know now that much can be done, much that is not done, for the accomplishment of these results. The world has, however, in action, never utilized its fullest capacity for work; in achievement it has never reached its power to do. This is true along all the lines of social and public activity. It is no more true in preventive medicine than in other departments of public endeavor. The great

difficulty in the way of successful sanitation has been, and still is a want of adequate knowledge as to the causes of our suffering, and the agencies of our destruction, and a want of confidence in the measures proposed for relief.

Of the beginnings of this desirable kind of knowledge we know but little, but in old records we find some faint suggestions. We know that along the eastern border of the old Ægean sea, and skirting the coast of Asia Minor are numerous islands whose names are embalmed in song or story of ancient Greece. On a high promontory of one of these, in the dim twilight of antiquity, a temple had been erected to Esculapius. A few miles back, at the base of a line of low hills, there gushed from the rock a stream of warm, life-giving water. Its properties were such as to invigorate and strengthen the wearied and exhausted, and to especially restore to the blood the qualities in which it is usually deficient in malarious countries. In a word, they were chalybeate. Rich in iron, they met most fully the needs of the dwellers along the shores of the islands and the continent, and the crowded cities of Greece. To this temple and fountain the sick from many lands had come, and there had been abundant opportunity to test the healing qualities of the waters. Those who had received benefit had hung upon the walls, or inscribed on tablets which were placed around the temple, brief histories of their diseases and the results of their offerings to God and Goddess. Here, in the fifth century before our era, a young student from a neighboring city, descendant of a long line of priest physicians, established his home. He was a lover of nature, and we may presume that he had been attracted in part by the beauty of the island, with its ridges of low mountains, or rather hills, which skirted the southern border, and which gave birth to cool streams of delicious water destined to give fertility to the northern slopes, the land of the grape, the home of the most generous of wines. The scholar had lingered, not so much for the beauty of the landscape, however, or for the delicacy of the fruits, as for the interest which he felt in the curative properties of the fountain itself. While he believed in the Gods, he was, nevertheless, a close observer of nature. Here in the temple had

already been established a school of medicine. The facts were the inscriptions just alluded to, placed upon the walls, left by those who had been cured by their visit to the temple and the grove, and in answer to their prayer to the deities of health and medicine. The young truth-seeker approached reverently the altar, but looked at the phenomena occurring under these influences as, nevertheless, the product of something in the world of matter. Time passed swiftly and happily in the pursuit of a more reasonable understanding of disease and its cause, and a more accurate knowledge of the instrumentalities by which it is modified.

His fame began to spread through the island and to the shores of Asia and Europe. Numbers came to consult him. His advice was sought in times of pestilence, and he had come to be regarded as one of the wise men of his age. Whether myth or history we know not certainly, but the story is that while he was patiently pursuing his studies and questioning nature, a messenger from the chief city of Greece landed upon the island. The angry gods, so the stranger said, had stricken in their wrath, the whole population. The peasant and the prince fell alike beneath the arrows of the destroyer. The chief ruler in his great distress had sent for the master. His favorite son had already fallen, and he himself had been accused by the people as the author of the scourge. He therefore prayed the learned man to visit the suffering city and advise what should be done to save, if possible, the remnant of the plague-stricken inhabitants.

In answer to the summons, the physician immediately prepared to leave his pupils, for he had already many such, and enter, as many of his followers have since done, the field of death. He gave a few simple instructions to those best fitted to carry on his work, and at once embarked. On reaching his destination, he found the city in a condition which the graphic pen of her chief historian has made to us so fearfully realistic. His first act was to note carefully the soil and drainage of the parts most severely afflicted. He also investigated the water sources. He studied the climatic conditions, and especially did he carefully note the occupations and habits of the inhabitants. He observed that filth everywhere abounded. While there was great magnificence in the architecture, and the palaces of the rich were in the most wonderful condition of adornment, there was beneath all this opulence of display a reeking hot-bed of foul matter giving off the most disagreeable and offensive odors. Under his advice there was an effort made to purify, as far as possible, the atmosphere. The city was besieged by an enemy, and the thickly crowded metropolis did not present a promising field for sanitary work. In the meantime, the great ruler, broken with his many cares and ill-

requited labors, was himself prostrated. The end was soon reached, and the greatest of the Athenians, Pericles, was among the immortals. Hippocrates returned to Cos, there to ponder upon the lesson which had been opened before him in the plague of Athens, and to write his book on "Airs, Waters and Places," the oldest treatise of which we have any knowledge on hygiene or public health. We find stated in it with almost the definiteness of modern sanitary science, the great importance of pure water, as well as some of the diseases which are likely to result from the presence of filth. From the time of the father of medicine to the revival of learning in the fifteenth century, we have but very little progress in the work of saving life. The older doctrines as to the cause of disease, whether among pagan or Christian people, were not encouraging to efforts in this direction. It has, therefore, come to pass that measures looking to the prevention of disease by the use of scientific methods, are modern.

#### BUT LITTLE DONE DOWN TO RECENT TIMES.

The maxims of Hippocrates, the ceremonial of the Hebrew law as to bathing, and the establishment of quarantines, are almost the only exceptions. For the most part suffering has been regarded as an infliction of the gods, or, among Hebrews and Christians, as a dispensation of Divine Providence. . . .

So long as life and its disorders were made to depend upon the unknowable, but little encouragement could be found, in fact for an effort to prolong the one, or to prevent the other. Even the materialists were content with phenomena, and wearily warred with existing conditions. Slowly with the revolving centuries better notions of the conditions of life have been reached. A better understanding and observation of sanitary laws has been brought about. Gradual changes in the modes of living and larger means of comfort on the part of the people have been accomplished. With all these improvements something has been done towards increasing the length of life. We have, as a race, made some progress, and by surviving we have demonstrated our fitness to survive. We do not know accurately the death-rate in the earlier centuries, but we do know that famine and pestilence carried away its hecatombs. As we come to more recent times we reach some approximation, at least to accuracy. In the seventeenth century, and for some hundreds of years before, the population of England and northwestern Europe had remained, if not stationary, with only a very slow growth. The cities, it is true, increased in population, but this increase could only be appreciated by comparing periods separated by many years. The agricultural districts very slowly became occupied. Life was short

and its product small. After the revival of learning, that great awakening of the sixteenth century, however, life became more valuable, and it was worth while to make a greater effort to save it. In the diaries of individuals and in the writings of medical men, we find some information, meager it is true, but some statements as to the life movements of the dead old centuries.

A few facts in the sanitary, or rather unsanitary, history of London during the seventeenth century, are suggestive of what was frequently taking place over all the then civilized world. These facts also give us a satisfactory explanation for the slow growth of the population of that century as compared with the nineteenth.

In 1625, a writer says: "The plague caused the death of 5,000 a week during a part of the summer." In 1665, July 16, he writes: "There died of the plague in London this week 1,100." In the week following, 2,000. August 8, he writes in his diary, "Died this week in London, 4,000." August 15, the same summer, "There perished this week, 4,000." He seems to have left the city for awhile, for on September 7, he says, "Came home. There perishing nearly 10,000 poor creatures weekly."

Sydenham, a very reliable medical authority, says of the same summer: "There died in one week 8,000, while two-thirds of the population were out of the city." The population is not certainly known, but probably at the time referred to was not more than half a million, as it was only something over 800,000 at the beginning of the present century.

Small-pox also ravaged the cities of Europe in winter, while plague decimated them in summer. In 1695, a reliable writer (Pepys) says, casually, in the discussion of other subjects: "The deaths were from small-pox increased to 500 more this week than last." What should we think in Brooklyn to-day with 500 deaths more this week than last from small-pox, with the probabilities that last week the number had reached into the thousands? But for vaccination, such might be our experience. The same writer comments upon the fearful spectacle in the streets of London. "Almost everyone," he says, "who has survived this scourge, was scarred and pitted by the pestilence and presented the most ghastly appearance." There was no effort to escape it except by flight to the country. It was believed that the epidemic constitution of the air, another unknown and mysterious quantity, made the plague a necessity once, at least, in thirty or forty years. Small-pox was always present and caused the death of one-sixth of the population of all the larger cities. The death-rate was greater than the birth-rate, and the population of London and other cities was maintained by a constant influx from the provincial districts. During all this time, the means of communica-

tion were few and *a priori*, we should not expect contagious diseases to spread with anything like the degree of rapidity made possible in this age of railroads and steamships.

#### ADVANCES IN THE LATER YEARS.

How much the death-rate has been reduced in England in the last two hundred years, we do not certainly know, but there is reason to believe that in London it has diminished from forty or more in the 1,000, at the beginning of the present century, to about one-half that number. The plague is a grim spectre of the dead past. Small-pox is a Samson shorn. The increase in population has been correspondingly rapid. I think we may safely infer that the diminution in the death-rate and the increase in the population throughout Great Britain has borne some proportion, at least, to what has been accomplished in the metropolis. This increase of population has taken place notwithstanding the fact that during the last half century, millions have come from the British Isles to our own shores, while yet other millions have found other homes, and yet the work-shops of Britain are beehives, and the hill-sides of merry old England teem with industrious workers. A great change has been wrought in this last three-quarters of a century. We know much more accurately how long people live, from what causes they die, and at what ages they die. We begin to see more clearly how the death-rate can be still more reduced. If we follow the course of a given number of individuals from birth to death, as we can well do by the aid of statistical tables, we shall find that in England and Wales out of one million persons born, more than one-fourth die in the first five years. If we divide the country into healthy and unhealthy districts, grouping together the different cities and counties according to the death-rate, we find that in the healthy districts only about one-sixth of the million die within this first period of five years, while in the unhealthy districts, of which Manchester may be taken as a type, nearly one-half of the million born, die within the first five years. In other words, of a million of children born in the unhealthy districts, more than 280,000 die within the first five years for the want of proper sanitary care; 280,000 would have lived beyond this five years if they had been born in the healthy districts.

The same startling contrast between the worse and the better districts, will meet us if we study the later life history of this 1,000,000 of human beings.

By coöperation on the part of the people the unhealthy districts might be made as healthy as London, and as the other provincial towns and shires in which the death-rate is so low. In fact, Liverpool has within the last twenty-five

years been transformed. It was one of the most unhealthy, it is now one of the most healthy of English cities. The application of money by scientific methods might change all this, and prevent this fearful slaughter of the innocents. . . .

#### LEGISLATION BASED UPON KNOWLEDGE.

The other field, and the one to which I more particularly desire to call attention, embraces the problems of public health. Society has always recognized certain evils growing out of aggregation, and has sought to control these evils. By legislative enactment and the establishment of police regulations, an effort has been made to secure the greatest good to the greatest number. Persons and property have been protected, crime has been punished; and mainly with the motive to prevent crime. In these later years the obligation of the public to protect, not only the worldly goods of the citizen, but also his health, begins to be realized. An intelligent foundation has been laid for sanitary reforms. These consist first, in the collection of statistics by which the value of certain procedures may be determined. The registration of births, deaths and marriages, the causes of death, the collection of information as to prevailing diseases, the collection and preservation of meteorological statistics, the collection and tabulation of statistics of the movements of the people, emigration, the growth of cities and States—all these accumulations serve as material out of which may be developed more accurate knowledge and better methods. Governments begin to recognize a responsibility in these matters. But for the most part, legislation is still crude, and the administration of sanitary laws full of blunders. In this respect the history of sanitary enactments and their execution does not materially differ from that of other social and political reforms. It is the want of accurate knowledge that leads to our mistakes of legislation; the want of practical acquaintance with the methods of administration that leads to the blunders to which we have referred.

As our oldest literature on sanitation was born of the pestilence, so our legislation has been stimulated by epidemics and has for the most part been provisional. Wise legislation must be based upon knowledge, knowledge on the part not only of professional sanitarians, but knowledge on the part of the public. It cannot be expected that this general or public knowledge will be technical; it must be general and related to the results that can be reached by scientific means and methods. A knowledge that begets faith in the agencies of protection and that secures efficient coöperation, and not, as has been too often the case, obstruction in the execution of sanitary laws. There are dangers, however, in this field of work, as in most others, that grow out of a smattering of knowledge. There will always be

those who claim too much, who speak as having authority, but have not the wisdom to see the limitations and difficulties in the way of practical results.

While, therefore, we should by all possible means strive to instruct and interest the great public in the work of preventive medicine, the task of devising the means and methods must remain in the hands of those who have special knowledge of these matters. These specialists should not be taken wholly from the profession of medicine. As an illustration of what a layman may do, I have only to mention the name of England's greatest sanitarian, Mr. Edwin Chadwick. Through a long life he has devoted himself to the work of improving the condition of London and other English districts, and it is safe to say that during the last fifty years his services have in value not been excelled by those of any Englishman in even the highest position of official or social life. What we want is on this side of the ocean such men as Mr. Chadwick. If we are to reach that measure of success which we believe to be possible, the world must not be left entirely to the medical profession or to health officers.

The egoism that leads manufacturers and others engaged in the various industrial occupations to ignore, in their eager pursuit of wealth, the public welfare, will always be an obstacle to the enactment and execution of health laws, but this general enlightenment on the part of the public which we so confidently look for, will compel obedience to these as well as to other forms of police regulation.

#### WHAT HAS BEEN DONE IN THE WAY OF LEGISLATION?

It is only within the last few years that sanitary organizations have come to be recognized as a necessary part of the machinery of State. Within the memory of many here present, there was not an efficient board of health in any city or State of this country, or in fact of the world. Police regulations establishing quarantine, it is true, existed, but these quarantines instead of being beneficent in their character, were often useless, and in many instances they became monstrous crimes against humanity. All this is being changed. Society recognizes its obligations in two directions: First, to remove from its midst or destroy every possible source of disease, and to so control the causes that cannot be removed or destroyed as to diminish to a minimum their deleterious influences upon public health. Secondly, the obligation to prevent the introduction of diseases from without, by such measures as shall be found the most efficient for the accomplishment of this end, and at the same time work the least amount of inconvenience to the social and commercial interests of the community.

For the accomplishment of the first purpose we have already done something, but there remains much more to be done. There should be in every town or city or district a health authority. Under the direction of this authority there should be a survey first made with a view to determine the presence or absence of the physical conditions that unfavorably affect health. This study should include not only the natural conditions, such as the climate, soil, exposure to sun and air, neighborhood, including water, wood and elevation, etc., as suggested by Hippocrates many centuries ago, but it should also embrace the condition of the population, their nationality, occupations, dwellings, density and food. It should also show the methods of removal of accumulations and, in the more populous districts, the disposal of sewage, the condition of streets and alleys, and the character of drinking water. There should also be noted any special industries by which air or water may be contaminated. The bearing of most of these different industries upon public health is now well known. In addition to these studies of the surroundings and the activities of the population, there should be a careful collection and preservation of the statistics of births, deaths, marriages, the prevailing diseases, the causes of death, and the increase or decrease, if such be the case, of population. This is only a suggestion of a few things that should be done, and these should be done in the smaller towns and villages, as well as in the larger cities. . . .

#### WHAT REMAINS TO BE DONE.

It appears that the death-rate of twenty-six of the principal cities of America, with a population of 9,873,448, is 20 per 1,000. I think it morally certain that this rate could be reduced, by means and methods *now known* to sanitary science, to 16 per 1,000, and probably still less than that. The death-rate for London for the year 1888 was 18.5 per 1,000. This can be still further reduced. That of New York and Brooklyn for the same year, taken together, was 25.5 per 1,000—New York 25.9, Brooklyn 23.7. The death-rate of these two cities, if reduced to that of London, would secure a saving of 7 per 1,000, or, annually, 15,986 lives. These lives are public wealth.

But this is not all. For one death annually two persons are sick during the entire year; or, in other words, there are two years of disabling sickness to one death—31,972 years, in New York and Brooklyn, of sickness, preventable sickness, annually. The value of these years of sickness cannot be reached with accuracy, but the wages lost on account of sickness, the cost of care and maintenance during sickness and convalescence, and the money value of the lives destroyed, considering them only as machines, will in New York and Brooklyn reach annually into the millions.

I venture to suggest to the business men of these cities that this loss is enough every year to buy a great railroad, or to build and subsidize a fleet of ocean-going steel steamships.

The sorrow of 16,000 homes, the years of grief, and the 32,000 years annually of anxious watching and waiting over the sick-beds of those who finally recover, are not taken into this estimate. Such considerations do not, except spasmodically, move legislatures or executives. It is only as these touch property, only as epidemics interrupt commerce, that we are able to secure efficient legislation. I firmly believe that the death-rate of nearly all our large cities may be reduced 3 to 4 per 1,000 from the present rate. I am fully satisfied that this might be accomplished in our chief cities, and that sickness might be diminished in a corresponding degree.

This lengthening of years, this relief of distress, this saving of public wealth, is worth working for. What is true of the cities is, to a great extent, true of the rural districts. All over our broad land are farm-houses and small villages which become every year the seat of diseases that grow out of filth. Foul drains, foul water, badly constructed and ill-ventilated dwellings and school-houses are the cause of thousands of deaths every year—deaths that might be prevented by the application of acquired knowledge upon this subject. Sir James Paget, before the London Health Exhibition, discusses the problem of national health, and very conclusively shows that among the wage-earners of England and Wales probably one-fourth of the sickness is preventable. Of the 20,000,000 of weeks lost by about 15,000,000 of the population, 5,000,000 weeks, or more than 95,000 years of work might be saved. This estimate is based upon the population between 15 and 65 years of age. The extension of this computation of sickness to all ages in Great Britain and Ireland would present us with a most startling array of figures. . . .

Up to the present time these problems of public health have received but little attention at the hands of statesmen; but it is no longer a question of possibilities, it is certain that this great saving of the best kind of public wealth is within our reach. It may not be accomplished by methods hitherto used, but the result is possible by methods that are known and which we know how to adopt. What we want is a recognition of the evil, and a disposition to invest at least a very small percentage of the loss in money value of life and work—wasted life and work—for the purpose of preventing this waste—hardly more than would be paid for the insurance upon our public buildings, or upon our dwellings in proportion to the value of the buildings themselves. . . .

We do not know with certainty how long life may be prolonged, but we are morally certain that it may be extended much beyond its present

limits, and with a fair degree of usefulness. It is believed that its normal limit is about 100 years. Instead of about 40 years under the most favorable conditions, as at present, it is quite probable that 60 or more years should be attained by the best use of the means now known; that is, the average should be 60 or more years. With a better understanding and more faithful observance of health laws 40 additional years should be reached. This obedience to law, this adjustment of our surroundings and regulation of our whole being, mind and body, in accord with the conditions of physical health, will prove to be the only true elixir of life. . . .

The future is full of hope. Everywhere science with the microscope and the crucible is following the germs of disease and the agencies of death. Politicians even are beginning to think it is worth while to preserve the lives of their constituents. The great public is beginning to believe that something more potent than fasting and sackcloth can be devised for their protection from pestilence and the grave. Let us all work together and we can do much even now, and in doing what we know how to do we shall find out other ways to do still greater things. So shall we lengthen the cords and strengthen the stakes of the great tent of life, under which the cry of distress and wail of bereavement shall become ever less and less; while in swelling chorus shall be heard, through the ages, the laughing of children, the sweet voices of young men and maidens, and the strong words of old men and matrons.

4 Sixteenth street, Chicago.

## ORIGINAL ARTICLES.

### THE CURE OF HERNIA BY THE USE OF THE BURIED ANIMAL SUTURE.

*Read in the Section of Surgery and Anatomy at the Fortieth Annual Meeting of the American Medical Association held at Newport, R. I., June 25, 1889.*

BY HENRY O. MARCY, A.M., M.D., LL.D.,  
OF BOSTON.

This paper is offered as a clinical study of operative measures for the cure of hernia. The cases reported represent all the usual varieties and were operated on during the eight months ending with April, 1889.

*Case 1.*—J. R., aged 45, an invalid for years from a large scrotal tumor. I had twice aspirated a few ounces of bloody fluid. There was also disease of the testicle. From the external ring there was a firm mass the size of the fist, continuous with the scrotal tumor. He had consulted several physicians, including members of the surgical staff of the Massachusetts General Hospital. Diagnosis uncertain, perhaps a malignant tumor; operative measures inadvisable. I operated

August 29, 1888, assisted by Dr. S. N. Nelson, of Boston. Removed the diseased testis; opened the hernial sac, which was found to contain only compressed omentum. Its folds were adherent, but were separated into the specimen here shown, which measures 6x8 inches. It was sutured across at its base, freed from adhesions to the internal ring, and divided. The stump was returned within the abdominal cavity. The large peritoneal sac was everywhere closely blended with the external tissues and was dissected with difficulty. It was freed to within the internal ring, well drawn down, and sewed evenly across at its base with five or six continuous sutures. This was excised and the closed peritoneum replaced within the ring. The internal ring was closed with a deep layer of double continuous tendinous sutures. A second layer of sutures was continued in the same manner, approximating the structures external to the pillars of the ring. The scrotal tissues were also closed by layers of buried continuous animal sutures. The skin was approximated subcutaneously by a blind stitch and the wound sealed with iodoform collodion. The operation, as were all of the entire series, was performed under strict antiseptic precautions, including continuous irrigation with a 2 per cent. sublimate solution. The wound healed without suppuration or even in any degree scrotal œdema. The patient was free from pain almost from the first.

At the discussion upon the subject of the cure of hernia in the Surgical Section of the Suffolk District Medical Society, January, 1889, Mr. R. kindly consented to be present and let the result be seen. The wound remains firm to date, the patient has resumed his ordinary occupation, suffers no inconvenience, and has not worn a truss. The sac in the specimen presented is stuffed with cotton and exhibits the peritoneal surface, in order to show the extraordinary changes that occurred in the development of its fibres.

*Case 2.*—M. H., aged 30, patient of Dr. C. W. Stevens, of Charlestown; is of exceptional physical development, fond of athletics. A large scrotal hernia of the right side, which for a considerable period has been irreducible and painful; incapacitated him at times for any labor. Had previously worn a variety of strong trusses with inability of retention. I operated September 29, 1888; opened sac, which contained an easily reducible loop of intestine and a large mass of compressed adherent omentum. The ring admitted two fingers. The operation was conducted as in case 1, except that, in the closure of the ring, the cord was gently lifted to one side and the internal ring closed from below upward, closely upon the cord at its entrance within the abdominal cavity. This was done in order to restore the obliquity of the canal. The cord was then replaced, and with the same suture the pillars of the ring were closed

down externally upon the cord, quite to the level of the external ring of the opposite side. The patient made a rapid recovery, the tissues uniting by first intention without œdema and almost without pain. Recent examination showed a slight bulging of the right inguinal region, but without opening of the canal. On account of a feeling of weakness and to prevent further yielding of the parts, he has been fitted by Dr. Codman with a light truss, which he wears with comfort.

*Case 3.*—J. M., age 55, coachman. He had been troubled with a right inguinal hernia for a long time, complicated with hydrocele, for the relief of which he has been frequently tapped; fluid withdrawn at the Massachusetts General Hospital a few days previous to operation, October 4, 1888. He was unable to reduce the hernia, and after two days of severe vomiting, the latter part of which was stercoraceous, he sought surgical aid. Taxis under ether proved unavailing. Assisted by Dr. H. D. Didama, of Syracuse, N. Y., I divided the constricting ring, restored the hernial contents and completed the operation for radical cure. After rallying from the ether the patient was taken in a carriage to his home, where he remained in bed two weeks, almost without attendance, but he made a rapid and painless recovery. He was also exhibited at the meeting of the Suffolk District Society above referred to. Although the hydrocele has twice refilled to inconvenient size, he remains entirely without discomfort from the hernia, has not worn a truss, and is actively at work.

*Case 4.*—S. N., physician, age 31, upon whom I operated for the cure of an inguinal hernia of the left side in the autumn of 1886, which has remained firm up to the present time. During the summer of 1888 he first noticed a slight bulging of the right side, for the support of which he applied a light truss. Notwithstanding, the hernia rapidly became scrotal and irreducible. I operated October 12, 1888, assisted by Dr. H. D. Didama. The sac was thickened, everywhere adherent, and dissected with difficulty. The loop of the intestine was easily reduced, but a considerable amount of omentum was adherent, and so changed that it was removed. The specimen here presented is interesting because of its rapidity of formation. The patient suffered extremely from pain in the back on account of confinement to the bed. For this reason he was allowed to sit in a reclining chair each day after the first, and in two weeks from the operation walked a quarter of a mile without inconvenience. The side feels perfectly firm at date. He has not worn a truss.

*Case 5.*—Mrs. J., age 40, entered private hospital on account of ruptured cervix and perineum. She had suffered also for years from a femoral hernia of the right side, easily reducible, but

which was imperfectly retained with a truss. In addition to the operations for repair of cervix and the perineum, I removed the hernial sac December 3, 1888, which is here exhibited. The recovery was rapid without any unfavorable symptoms and the patient remains cured at date.

*Case 6.*—G. S., age 40. The general health of the patient excellent, but for years he has been incapacitated for active labor because of a large left inguinal hernia, complicated with a varicocele. The scrotal tumor is so large as to extend at times quite one-third to the knee. The hernial tumor is imperfectly retained by a truss, the pressure of which causes pain by impeding the venous outflow. Assisted by Dr. H. D. Didama, of Syracuse, N. Y., I operated December 4, 1888. In addition to the operation for the radical cure of the hernia I dissected and tied the veins of the scrotum in three different places, some of which were varicosed to the size of the little finger. The wounds healed without œdema or suppuration, but the scrotum remained somewhat tender to pressure, and the patient still wears a suspensory bandage. The patient remained in the hospital three weeks and was discharged cured. No return of or inconvenience from the hernia, and no truss has been worn. Is actively at work.

*Case 7.*—Mrs. J. S., age 43. For many years has suffered from a right femoral hernia, for which she had worn a truss. For the last year she had noticed a tumor in the groin, something larger than a hen's egg. At times it is painful and always a source of discomfort, is slightly tender to the touch, and does not diminish under pressure. Femoral canal admits the tip of the little finger. Operation performed January 2, 1889. Sac contained clear serum and was continuous above through the femoral canal with the peritoneum, but its cavity had been obliterated under the pressure of the truss, thus reducing it to the characteristics of a simple cyst. This I removed and closed the ring. Rapid primary union followed, and the cure remains complete without support. Specimen exhibited shows the intimate adhesion of the sac to the surrounding tissues.

*Case 8.*—Mrs. B., age 34. Has for a long time been a semi-invalid from a right femoral hernia, for which she has worn a truss. In preparation for moving she lifted more than usual, causing the descent of the hernial tumor, which immediately produced great suffering, with faintness and vomiting. The physician summoned to her relief attempted the reduction of the tumor by taxis, which he continued more than an hour. His efforts proved unavailing and he left the patient with directions to use opiates and hot fomentations. I was summoned twenty-four hours later, January 31, 1889. At once I removed her to hospital, etherized and operated. The ring was divided with difficulty and several inches of congested

intestine liberated and returned. The patient made an excellent recovery, although between three and four months pregnant at the time of operation. She remains cured at date, although nearing her delivery. She has not worn a truss. The sac here exhibited shows the constriction of the neck, through which a piece of rubber tubing has been passed.

*Case 9.*—Strangulated umbilical hernia, five days' duration; patient of Dr. J. H. Parks, of East Boston. Case came under his observation only a few hours prior to his sending for me in consultation. Stout Irish woman, aged about 50. For some years had suffered from an umbilical hernia, double fist's size, a portion of which for a considerable period had been irreducible. Stercoraceous vomiting had continued for two days. Operation considered permissible, although the result would be doubtful. The thin-walled integuments covering the tumor were sphacelated. The hernial contents were found to consist of a large mass of adherent omentum, within which a considerable loop of small intestine was incarcerated. The constriction was easily divided, but the intestine was gangrenous and tore asunder under gentle traction. The ends were brought out from the wound, resected, and coaptation affected by means of a double row of continuous Lembert sutures. These were easily and rapidly applied and the divided mesentery united in continuous suture. The parts were well washed with hot sublimate and returned within the abdomen. The hernial sac was resected and the abdominal wall closed in layers by continuous tendon suturing, as after an ordinary laparotomy. When partially recovered from ether regurgitating vomiting occurred, several pints of dirty fluid, which was so continuous as to impede respiration and, despite all efforts, proved the cause of death. In order to anticipate such a possible accident it had been the intention to wash out the stomach prior to etherization, but in the hasty preparation the stomach tube had been unfortunately forgotten.

*Case 10.*—I. J., aged 75. Strangulated left inguinal hernia. Retired sea captain; general health good. Has for years suffered with double inguinal hernia, imperfectly retained by a truss. About four weeks prior to operation the left hernia became strangulated and, under ether, was reduced with difficulty. I was summoned shortly after the strangulation occurred. Failing in taxis I operated at once, March 7, 1889, assisted by Drs. Nelson and Cook. The tumor was double fist size and reduction was effected only after a wide division upward of the constricting ring. The sac contained about fifteen inches of small intestine, closely adherent by lymph exudation, probably dating from the strangulation of four weeks previous. Adhesions broken down prior to the return of the intestine into the ab-

domen. Vomiting ensued soon after the close of the operation, and insufflation of a portion of the liquid contents into the bronchi well nigh caused death. Acute pneumonia supervened, which caused the greatest anxiety for the two subsequent weeks. Although the strain from coughing was severe, the sutures did not yield, and yet, ten days after the operation, a considerable portion of devitalized, broken-down tissue was exfoliated. Repair went on satisfactorily by granulation, although the recovery was necessarily protracted. A considerable depression marks the site of the wound, but the abdominal wall is firm and unyielding. The patient is actively about, wearing a truss to support the opposite side. The accompanying specimen shows the everted sac stuffed with cotton and nearly fills a quart jar. The peritoneum affords an interesting study.

*Case 11.*—Mrs. P. Right femoral hernia. I operated upon the lacerated cervix and restored the perineum at the same sitting, April 17, 1889. Recovery rapidly followed, the patient apparently suffering little or nothing more from multiplicity of operations. Union in each primary. Specimen exhibits an interesting condition of the changed peritoneum. The patient returned home, several hundred miles distant, at the expiration of three weeks, and reports condition satisfactory.

*Case 12.*—Right scrotal hernia. Patient aged about 60, inmate of the Soldiers' Home at Chelsea because of this disability. Operated upon by Dr. Nelson and myself April 10, 1889. Sac everywhere adherent. Dissected with difficulty. Obliquity of canal restored. Recovery slow, but result reported as satisfactory. The accompanying specimen exhibits the peritoneal sac most remarkably reinforced by interlacing bands of hypertrophied connective tissue.

*Case 13.*—Right femoral hernia. Female aged 27; seamstress. Hernia retained imperfectly by a truss. Disability and suffering very pronounced. Operation April 27, 1889. Recovery rapid; discharged from the hospital at the close of the second week, and she has resumed her ordinary occupation.

*Case 14.*—Miss N. C., aged 28. Large ventral hernia. In August, 1886, I removed a multiple ovarian cystoma weighing about 30 pounds. Incision was 3 inches in length. Wound closed by interrupted sutures taken through the entire thickness of the abdominal wall. Following the recovery the patient rapidly gained 40 pounds in weight. Ventral tumor at time of operation, May 10, 1889, nearly the size of an adult head. Resected the sac and closed the abdominal wall by continuous tendon sutures in four layers, the skin with blind stitch. Sealed the wound with iodoform collodion, as in all the previous cases. Patient made rapid recovery and was discharged from the hospital in two weeks, wearing an abdominal support. The specimen of the cyst

shown, exhibits remarkable diverticuli. The lower portion of the sac was filled with a mass of adherent omentum.

The series of cases reported above, operated upon within eight months, include all the usual varieties of hernia. They complete a list of operations, now numbering nearly 100, which I have performed during the last eighteen years. The method followed, from the first, has been subject substantially to the same factorage, although varying somewhat in detail.

Since I have recently given to the profession my views upon the conditions, symptoms and treatment of hernia at length,<sup>1</sup> I shall limit myself in this paper to a brief discussion of what I deem to be the essentials of the operation for the cure of hernia. I do this with the greater interest and pleasure since the cure of hernia is confessedly an opprobrium of surgery, and it is not until a very recent date that surgeons in either Europe or America have been willing to discuss seriously the advantages to be derived from operation.

In 1878 I first reported to this Association my method, illustrated by a series of cases with specimens, which have been supplemented, from time to time, by further contributions until the present. The basic and fundamental factor consists in closing the divided and weakened structures by strong sewing with a carefully prepared animal suture after the removal of the sac. This is aseptically applied and approximates the refreshed tissues by layers of buried suturing, so as to avoid the necessity of drainage, and thus allows of the complete closure of the wound, hermetically sealed with iodoform collodion, a very simple, but germ-proof dressing. I first published it in the *Boston Med. and Surg. Jour.* in 1871. My first case thus operated upon was in 1870. In this case the use of the buried suture was accidental and applied to serve a temporary purpose, but a permanent cure resulted. After mature deliberation I judged it sound surgical practice thus to attempt the cure of hernia, and other equally successful cases thus treated soon followed, the first fruits of my personal instruction received from Prof. Lister in Edinburgh, in 1869. He had limited his studies at that time to the results of the ligation of arteries by catgut left buried in the wound. I extended the use of the catgut ligature to the approximation of tissues, and made a series of experimental studies in animals upon the changes in the tissues which ensued. I determined that, when properly prepared, if aseptically applied, they were slowly replaced by bands of living connective tissue, and thus served an important purpose in the reinforcement and strengthening of the parts involved. The use of

the suture thus applied to hernia, is naturally of very great value for the approximation and retention of all wounded surfaces. In aseptic wounds it now promises to do away entirely with drainage and the multiplicity of antiseptic surgical dressings.

Under the new régime of surgery, in competent hands, the claim for operative measures for the cure of hernia may be strongly made:

*First.*—It is eminently a safe operation. In my own experience, extending through all these years, in all cases operated upon where the integrity of the intestine was not involved, I have not had a fatal case, or one where it appeared that even the danger line was in any way approached. In my recent work upon hernia above referred to I have collated, as far as possible, all the reported cases of operation under aseptic precautions. From the reports of recent operators I find 779 cases of hernia which have been operated on for a variety of causes, with only five deaths, and these are explained as having resulted from conditions not referable to the operation. This contrasts so extraordinarily with the earlier experience of the profession, when, usually, all hernial operations were septic and peritoneal infection the rule, often followed with fatal issue, that the modern operation for hernia may be claimed as one of the greatest triumphs of aseptic surgery.

*Secondly.*—The results of the attempt at radical cure are almost equally surprising. I have found it quite impossible to trace the subsequent history of every patient, but recent investigation shows that of those of whose histories I have a knowledge fully 90 per cent. are permanently cured, and in no instance do I advise the subsequent wearing of a truss. The essentials of my operation are briefly as follows:

The hernial sac is opened, its contents restored to the abdomen, or removed, and it is freely dissected to its very base within the ring. The sac is then drawn down, sewed across with an even continuous double suture, resected and removed. The peritoneum is then carried quite within the ring. (Fig. 1.) In large direct inguinal hernia it is important to restore the obliquity of the canal, nature's wise provision for maintaining the closure of the canal by intra-abdominal pressure in health.

This is effected by commencing at the lower and inner border of the ring, the cord having been gently laid to one side, and closing by double suturing quite to the inner opening of the ring upon the cord, which is now replaced, and the external pillars of the ring are closed by similar suture downward and inward to the pubic tubercle. The inguinal rings are thus reformed and the canal is restored to its normal oblique position. (Fig. 2.) If the tissues are sufficiently thick to warrant it, a further layer of animal suturing completes the closure, and the skin is neatly and accurately approximated by a blind running

<sup>1</sup> A Treatise on Hernia. The Radical Cure by the Use of the Buried Antiseptic Animal Suture. 1889. G. S. Davis, Detroit, Mich.

FIGURE I.—Represents the introduction of the first stitch, taken to close the ring from below upwards in order to restore the obliquity of the canal.

stitch, perhaps best applied with a fine Hagerdorn needle, taken through from side to side, including only the deeper layer of the skin. This completes the closure of the wound, each step of which is done under irrigation with a weak sublimate solution, and without the vestige of a stitch in sight. The incision is now dried, dusted with iodoform and covered with iodoform collodion, into which a few fibres of cotton are incorporated. No further dressing is necessary.

Femoral hernia is treated essentially in the same manner. Here it is necessary, after the removal of the sac, to close the ring. Protect the femoral vessels in their sheath by pressing them gently outwards, and introduce the needle, as directed in inguinal hernia, from below, through the falciform process, the fascia lata, avoiding the internal saphenous vein, upwards through Poupart's ligament, withdrawing the opposite end of the suture with the needle. (Fig. 3.) A second stitch is taken through the same tissue, parallel to the first, about one-fourth of an inch nearer the median line. The third stitch is introduced through the *pubic* portion of the fascia lata, paral-

lel to the saphenous vein, and is carried upwards to include Gimbernat's ligament, or its divided fibres if cut in strangulation. (Fig. 4.) A fourth, and as many more stitches as may be required to close the saphenous opening, is carried below and parallel to Poupart's ligament, through the pubic fascia and falciform fascia. In this way the peritoneal pouch is obliterated and the neck of the sac firmly closed.

The folding over of the fascia carries the saphenous opening quite a little to the inner side of its former site, while the femoral vessels are undisturbed in their sheath. (Fig. 5.) The superficial tissue and skin are closely held in conjunction by buried continuous animal sutures and the wound dressed with iodoform collodion, as advised in inguinal hernia.

If the cure of hernia is to be attempted under modern surgical methods, most surgeons will readily admit that it should be by a free dissection, or the open wound method, under rigid antiseptic precautions. Modern operators are divided in opinion as to the treatment of the sac. All are determined that it must in some way be

FIGURE II.—The internal ring closed. The completion of the last deep stitch of the double continuous suture.

disposed of. Most advise ligation at its base and removal. Mr. Ball, of Liverpool, and his followers, twist it firmly upon itself, in order to render tense the peritoneum of the abdominal wall before ligation. Mr. MacEwen, on the contrary, whose brilliant results challenge admiration, advises the careful dissection of the sac, folding it back upon itself by a running catgut suture and then, with a needle with eye near the point carried through the peritoneum above the internal ring, the whole sac, puckered into folds, is drawn within to serve, as he thinks, as a buttress for the further protection of the internal ring. The advantages of this method are probably theoretic rather than real. The use of the sac as a plug to close the ring, there sutured and retained, has very generally been abandoned as unsatisfactory. Utilized as proposed by Mr. MacEwen, if it forms a buttress, as supposed, to receive the intestinal impulse, may it not be equally inferred that it would be likely to act as a wedge to press unevenly against the newly formed tissues of the restored canal, and thereby cause harm rather than serve as a deflector of pressure? Although the peritoneum forms a pouch or pocket surrounding the hernial contents, nature did not intend it to

serve as a part of the supporting abdominal wall, but by an even elastic, smooth surface lining the firm muscular and tendinous structures to allow the abdominal contents to glide easily and evenly in every direction. As will be seen by the specimens exhibited, in a very considerable number of cases of old hernia, the disposition of the sac, as advised by Mr. MacEwen, would be quite impossible. In illustration in Case 10, where the sac is nearly the size of a child's head at birth. Again, also, the sac is so intimately blended with the surrounding tissues that, with all due care in dissection, it is so devitalized and injured that, even if aseptically restored within the internal ring, its presence could furnish only a doubtful factor toward the subsequent repair of the parts. On the other hand, not seldom, especially in children, the sac is so thin and unimportant that it may often be comparatively immaterial in what way it is treated.

Normally the internal ring is ovate, and in closing the sac at its mouth it is doubtless better to do this in the direction of its longer diameter, which gives as the resultant a smooth rather than a puckered peritoneum, in the largest degree vitalized and resilient, freely movable upon its exteri-

FIGURE III.—Femoral hernia. The first stitch taken parallel to the vein for closing the crural ring.

only loosely attached fascia. In the attempt at this normal restoration no method, theoretical at least, is equal to that of closing the mouth of the sac in continuous seam. Good results, however, follow all the various ways for the obliteration of the mouth of the sac at the internal ring. The method of sewing may be in considerable variety. The simple over and over stitch will give good results. I cannot doubt, however, that the closure of the canal and abdominal wall by my method of suturing with double stitch has certain marked advantages. It is equally simple in application and carries a double thread, like the shoemaker's stitch, from opposite directions, through the same opening. The approximation of the tissues thereby is even and uniform, and necessarily nothing can escape its grasp. The continuity of stitch renders equal pressure, an important gain over the interrupted suture, while a single knot only is required. It is necessary to use a needle with the eye near the point, which must also be in considerable curve. To avoid unnecessary multiplicity of instruments, I have had the larger size of Hagedorn needle drilled with eye near the point, which serves a very good purpose. It is, however, more convenient to have the needle set in a firm handle as here exhibited, and I have found a certain ad-

vantage in continuing each end of the eye in a narrow slot in order to catch and hold the thread from slipping. (Fig. 6.) Well prepared catgut may be safely used in this operation, however, I cannot doubt that the tendon suture, especially that prepared from the tail of the kangaroo, is in every way greatly superior.

When to operate is a subject of the greatest interest, but the limit of this paper must necessarily debar its discussion. Judged from my own experience, the operation is permissible in the very large proportion of all the sufferers from hernia. There is much to be said in favor of operation upon children. Certainly in adults all hernia imperfectly controlled by a truss should be carefully considered from the view of the advisability of operation. In the old large hernia, irreducible in great measure, rendering the sufferer incapacitated for all active pursuits, the operation should be advised.

Adherent omentum is likely to be so much changed as to render its return to the abdominal cavity ill-advised, but the removal of it appears to add little to the danger of the operation. Age *per se* should not debar operation. I have myself operated upon one child of 16 months who, after recovery from ether, gave little evidence of any discomfort. Several of my patients.

FIGURE IV.—Femoral hernia, showing a third stitch taken for closing of the canal by the use of the double continuous tendon suture. The stitches are represented as loosely drawn in order to show the method of suturing. The needle is passed through the firm pubic fascia and the outer border of the saphenous opening, and when drawn closely will fold the latter inwards.

FIGURE V.—Shows the internal ring closed by the double continuous tendon suture. Stitches loose to show method of suturing.

have been past 70. My friend Dr. L. S. Pilcher, of Brooklyn, has twice operated, followed with complete cure, upon patients, each over 80 years of age. Dr. John H. Mackie, of New Bedford, writes me: "I operated on a man aged 83, right inguinal hernia, strangulated; recovery perfect, but one year later I operated on the same man for left strangulated hernia and he made a good recovery, living several years."

The advisability of operation in any given patient is always to be seriously considered as an independent problem, the factorage of which must consist of many individual details. There is little question that the large percentage of sufferers from hernia will profit from the surgery of the near

future whom the conservative surgeon of to-day conscientiously relegates to the truss bearing army of invalids.

DR. T. H. MANLEY, of New York City: With reference to Dr. Marcy's paper there are a few points on which I wish to make a few comments. They are briefly, first, that the method described and practiced by him is no open method at all, and has no claim to any such designation. The next is, that though Dr. Marcy has fair results, there has been no mention of the operation of Dr. Chas. McBurney, of New York, which is the *only, real* open method applied in the operations of hernia. By this method McBurney has now operated

more than forty times, with only one death—which had no connection in any way with the operative procedures—and with only one return of hernia. McBurney, instead of endeavoring to secure immediate union, purposely prevents it, and always *aims at* healing the furrow from the bottom, by keeping the wound margins separated till the granulation and cicatrization of tissue has progressed towards the periphery of the wound.

With reference to suture material, while I find catgut useful when primary union is sought for, where there is any tension put on the suture or where there are large blood-vessels to close, it should not be used, owing to its tendency to either disintegrate, or strip away.

The ideal, the simplest and, *every way* considered the safest method, I think, yet known for operating in cases of strangulated hernia, is McBurney's. Here, every time, we can promise *permanent* cure, if the patient survive operation. But he must be operated on early. General practitioners, when they encounter hernia resisting taxis, and threatening to become constricted, should advise *immediate* operation provided the patient's general health is good. He can effect a radical and speedy cure here, which in itself entails no danger to life. I have applied the McBurney method in strangulated cases. I have operated during the past spring three times for strangulated hernia by the open method; two recovering and one dying, who was practically moribund when he went under ether.

Both surviving, with their hernias permanently closed, and being confined to bed only twenty-eight days in each instance.

DR. J. O. WHITNEY, of Pawtucket, R. I., said there is no such thing as congenital hernia. It is due to straining from crying, or at urination with adherent prepuce. If the prepuce be split up no trusses are necessary.

DR. H. D. DIDAMA, of Syracuse, N. Y., had been present at several of Dr. Marcy's operations. The performance was as described by him. The stitching was so complete that a return of the hernia was impossible unless the tendon should be absorbed too soon and give way. But his experience has proved to him and should satisfy us that this tendon never gives way, and that we need not lie awake fearing any bad result from this source. He uses no drainage whatever and never needs any. He never removes a suture because none ever appears on the surface of the skin. There are never any stitch abscesses which are so common in laparotomies performed by sewing through the entire thickness of the abdominal walls.

Dr. Marcy's operation does not confine the patient to the bed for a long time, sometimes not more than two or three days, and there is no pain in any considerable number of cases, and not even inconvenience. His operation seems simplicity

simplified and a temptation to any one who has a hernia, even if it gives him no trouble.

DR. JOSEPH H. WARREN, of Boston, Mass., said: While I endorse in general the operation of suturing advocated by Dr. Marcy, I have certain points of technique in my own method essentially differing from his method which I will mention.

I am aware of the claims advanced for animal sutures, but I have always feared their advantages might be too great and the absorption claimed for them might be premature. I have used those furnished by Dr. Marcy himself first in a case of ovariectomy, and I passed sleepless and anxious days and nights in consequence. The constant dread of the melting away of the ligatures, although perhaps not probable, was sufficiently possible to give me no rest until the patient was beyond doubt cured. The case was especially dangerous, as acute mania set in and the patient persisted in tossing and kicking about, to the total destruction of a mechanical bed which I used for such cases and with imminent danger of destroying herself. Still, the ligature held, and I presume this would be construed as a success by one in favor of animal ligatures. Still the uncertainty remains.

Another objection to the animal ligature is the large size compared to silk of the same strength, and the consequent large needle necessary for its use. In my own operations I use braided silk, and feel secure when the parts are approximated they will stay so until united.

The essential difference in my method is the style of lacing. The sac and omentum are included in a gathered suture, the silk being run in from both sides like the puckering string of a bag. Redundant tissue is cut off with scissors just below the stitch. The mass is then returned, the two ends of the suture being left outside and the mass drawn down by them to the internal surface of the ring. A series of stitches is taken in the edges of the ring, each suture being interrupted, all passing each other at the centre, forming a multiple cross or star-shaped plan. This is the first stage. After this I insert a series of stitches superimposed upon the first, each stitch being taken some distance back from the edge of the ring, the stitch not passing entirely through the muscular walls but entering the surface, passing backward and coming out beyond the point of entrance about  $\frac{1}{4}$  inch. These stitches are tied sufficiently tight to pucker the tissues and infold the muscular tissue at the site of the ring. This results in a raised cicatrix, the elevation pointing toward the abdominal cavity and rendering a recurrence of the hernia at that spot less likely, whereas in the plain lacing of the tissue a depressed scar results which offers a constant *point d'appui* for the intestines to work against, and sooner or later may allow the entrance of the wedge and consequently rupture.

This reduplication of tissue also gives a larger uniting surface, the edges and contiguous surfaces being freshened that adhesion may more readily take place. This freshening is most completely done with scissors or scraping rather than with a sharp scalpel, it being my experience in special and general surgery that torn or roughly dressed tissues heal more readily than those cut with sharp, keen scalpels. My preference for the fingers or tearing instruments in place of sharp instruments is founded on good results obtained by this method, and this is especially the case in the cutting of arteries and veins. When put on the stretch and thus severed the vessel is closed so effectually that in my own practice I have never had a case of secondary hæmorrhage, and the primary loss of blood is very slight.

At one time I advocated the use of the galvanocautery in securing a consolidation of the hernial rings. Several cases were successfully treated by this method, and should a very large hernia with weak walls present itself I think I should still prefer this method. The adhesive and contractile power of a burn is well known, and it is as powerful in the hernial rings as elsewhere.

In ordinary cases the freshening and lacing is sufficient. In the majority of cases I still adhere to the subcutaneous injection, and in selected cases, those of good physique and where the hernia is small and of recent occurrence, I still have good results, a ratio of 96 per cent. Its failure in the hands of some operators is not due to the operation. It is due to the selection of cases in the first place that ought never to have been attempted; and secondly it is due to non-observance of minor matters of technique. While I have given its description in the plainest manner possible, I am convinced that there are elements of technique which can be caught only by intuition or careful clinical instruction. The fact that it is practiced by advertising specialists with advantage to the patient and pecuniarily to themselves, and that they claim to have license from me (a claim not founded on fact), proves that there is some good in it.

My name has unfortunately become so firmly united with the operation by injection that many think I advocate no other method and practice no other part of the profession. This is untrue in both cases. My motto is to choose the best for the case in hand, and I would not for a moment be prejudiced in favor of any pet method to the prejudice of the case. The case in all its details determines my method of procedure.

DR. H. J. HERRICK, of Cleveland, O., said: I have taken much interest in the papers presented looking to the relief of this distressing and frequent danger to which so many are subject. Most of the cases reported are of those which have come under the care of the surgeon when the emergency was upon them. In this connection I

desire to call attention to that large class of cases in which the hernial tumor is so large and the opening so patent that strangulation is not and is not liable to be present, but, on account of the size and inconvenience as well as danger of inflammation, life becomes intolerable except as it may be devoted to nursing this as yet almost hopeless infirmity.

Have we not a duty towards this class of sufferers? In illustration of the points indicated I will mention the following cases: A young man 28 years of age came to me from a neighboring city with a double scrotal hernia each side of which was the size of the two fists, the openings so great that the gut could not be retained with any appliance. Patient was anxious for matrimony and the business of life, yet with the existing deformity could not. I advised an operation for the radical cure. Not being satisfied with any of the concealed, obscure and empirical means that had been devised, I proposed an open radical operation, which I made upon both sides at the same operation. With antiseptic precautions I made an incision along the neck of the sac 3 inches in length, dissected my way to the sac, emptied it of its contents, at the same time drawing it out. Holding the empty pouch I applied a temporized clamp made by the handle of a dressing forceps closely to the neck, then amputated the sac near the clamp, leaving space for the closing of the neck with a continuous suture, with care to bring the edges of the amputated sac in apposition. The ligature used was the iron dyed silk. Thus the peritoneal cavity was kept closed from the entrance of air, fluid or any septic material. The edges of the ring were made bare and brought together with an interrupted suture of the same material. In the same way I brought together the divided parts of the deep fascia, also superficial fascia and connective tissue and finally the integument, taking special care to leave no contused or lacerated fibres, remove all clots and bring together gently in apposition all the divided parts. No drainage tube was used. Antiseptic dressing was made. The case proceeded to recovery with no unfavorable symptoms, temperature having reached only 100°. In two weeks' time the wounds were entirely healed, with no suppuration. After three weeks, patient returned to his home, since which time he has pursued his former plans of matrimony and business with no return of the hernia. About two months ago a woman with an inguinal hernia of the left side came to me. The tumor was the size of the two fists and involved the left labia, which was very greatly distended and tumefied. It could not be retained by truss, and being required to gain her living by work she expressed the feeling that she would rather die than endure the suffering and care necessary. I advised the open operation for radical cure, to which she con-

sented. The operation was performed two months later in substantially the same manner as in the previous case. The large pouch of the labia was treated antiseptically with a bichloride solution, with the expectation that no suppuration would occur. Owing to its size, tumefaction and inelastic structure suppuration followed and came near destroying the hopes in the case. The inflammation did not extend to the line of deep incision, but was limited to the pouch of the labia, which being opened freely, cleansed and washed with sol. carbolic acid, inflammation subsided and all dangerous symptoms subsided, so that patient before I left home was up, parts perfectly healed, and discharged from the hospital apparently well. It is too early at present to speak assuredly of the absolute success of the operation, though all appearances at present justify the fullest hopes.

I used in this last operation the clamp used for the treatment of hæmorrhoids and found it a most appropriate instrument. By reason of the handle it enabled the assistant to hold the part in the most convenient way for suturing, and the thumb screw enables the surgeon to regulate the pressure to be applied so cautiously as not to endanger the integrity of the parts.

Feeling that the profession has a new duty to perform to this class of unfortunates, these cases in this connection may not be amiss.

DR. MARCY, in closing the discussion, said that the large number present at this late hour (nearly midnight) shows the interest which American surgeons have in the subject under debate. He would detain the members but a few moments, although many points of both interest and profit had been alluded to only briefly. He would ask a critical examination of the specimens of the peritoneal sac which he had been to the trouble of bringing, since they showed important pathological changes which appeared recently to have been, in a large measure, overlooked. They are of the first importance to understand if we are to utilize the sac by any method of surgical procedure. Cloquet, in his masterly work, emphasized the great changes which the sac in old herniæ usually presented. Dr. Mauley evidently entirely misunderstood the use Dr. Marcy made of the words open wound. This was in contradistinction to subcutaneous methods of treatment, as by the yet too generally accepted plan of Dr. Wood of subcutaneous closure by the wire suture, or the methods of cure by injection. He was quite familiar with Dr. McBurney's operation, and had only recently carefully reviewed his method, showing what he thought were primal faults. Elsewhere, in all parts of the body, the aim of modern surgeons was to secure primary union, and it would indeed be strange if a hernial wound should prove an exception. Why not adopt this plan in the closure of all laparotomies, if so greatly to be preferred. Dr. McBurney's

method has found advocates chiefly because the hernial wounds, as ordinarily dressed, are very liable to become infected. Dr. Warren has referred to the large size of the animal suture, as compared with silk, which is necessary to be used. This, in a measure, is true if catgut is used, but does not apply to tendon. On the contrary, the tendon suture, the size of silk, is very much stronger, as may be tested by the samples here shown. Dr. Pancoast has just made an eloquent plea for the use of his iron-dyed silk. However he, with most others, admits that it generally must be removed. At the best, silk is encapsuled, while the aseptic animal suture is replaced by bonds of living connective tissue cells. Upon this fact, long since demonstrated, is based, in a large measure, the method here advocated, and it is not too much to believe that the profession will early accept the great gain resulting from the use of the aseptic animal suture in the coaptation of all aseptic operative wounds.

Blind surgery is bad surgery. As advocated, each step of the operation is directed by seeing the exact condition of the parts. The reformed peritoneum is carried within the firm tissues of the abdominal wall. The inguinal canal is reformed. The refreshed pillars of the ring are closed in even continuous suture. The coapted skin is covered by a layer of germ-proof iodoform collodion. The wound, if aseptic, remains so, and Dr. Warren may rest undisturbed by dreams or visions of discontent, while the patient in security goes on to rapid convalescence.

#### A PLEA IN FAVOR OF EARLY LAPAROTOMY FOR CATARRHAL AND ULCERATIVE APPENDICITIS, WITH THE REPORT OF TWO CASES.

BY N. SENN, M.D., PH.D.,

OF MILWAUKEE, WIS. PROFESSOR PRINCIPLES OF SURGERY AND SURGICAL PATHOLOGY IN THE RUSH MEDICAL COLLEGE, CHICAGO, ILL.

The literature of the surgical treatment of affections in the ileo-cæcal region has been increasing very rapidly during the last few years. A great deal has been said and written concerning the propriety of surgical interference in cases of perforative appendicitis, typhlitis, paratyphlitis and perityphlitis. Post-mortem examination and clinical experience have demonstrated that with few exceptions localized and diffuse peritonitis as well as suppurative inflammation of the connective tissue originating in the ileo-cæcal region, are caused by an antecedent affection of the appendix vermiformis, which has resulted in perforation or gangrene of that structure. While it cannot be said that unanimity of opinion exists among surgeons in reference to the exact indications for

operative treatment in cases of appendicitis and suppurative perityphlitis, it is safe to assert that the majority of them would not hesitate to resort to the knife in every instance where it would be possible to ascertain beyond a doubt that perforation had taken place. Numerous cases have been reported during the last three years where prompt action on part of the surgeon has been the means of saving life in cases of phlegmonous inflammation and circumscribed peritonitis caused by perforation of the appendix vermiformis; but, on the other hand, many laparotomies for diffuse peritonitis due to the same cause proved powerless as a life-saving measure, because the direct invasion of the peritoneal cavity had given rise to a diffuse septic peritonitis alike beyond the reach of medicinal and surgical measures. The principal object in writing this paper is to call the attention of the profession to the necessity of treating the primary disease of the appendix by radical measures before the advent of incurable complications, that is, before disease due to perforation has occurred. I believe that in many cases the development of perityphlitis is preceded by a well-marked complexus of symptoms pointing directly to the existence of appendicitis. Many patients suffer from well-defined symptoms indicative of the presence of an inflammatory lesion of the appendix for months and years before it gives rise to a perityphlitis or perforative peritonitis. It is of the greatest practical moment to recognize the exact condition in time, and to anticipate the dangerous and only too often absolutely fatal complications by removing permanently the source of danger which can be done at this time with comparative ease and almost perfect safety by the extirpation of the appendix.

The following cases will serve to illustrate the correctness of these assertions:

*Case 1.*—J. S., 22 years of age, clerk by occupation, came under my observation during the last week in April, 1889. He consulted me at my office, and informed me that during the last fifteen months he had suffered from five attacks of what his physician called perityphlitis. Each attack was attended by excruciating pain in the ileo-cæcal region, vomiting and constipation, and usually lasted from one week to twelve days. During the intervals he was able to follow his occupation, but never quite regained his former health. The treatment consisted of rest in bed and opiates. Between the attacks the bowels moved regularly, and the patient was free from pain. At the first examination I found the temperature 99.2° F., pulse 80, tongue heavily coated. Patient somewhat emaciated and pale. Pain was referred to the ileo-cæcal region, and directly over the location of the appendix vermiformis a circumscribed area of tenderness could be mapped out. Palpation and percussion failed

to show any appreciable swelling, but on deep pressure while the patient's chest was elevated and thighs flexed, a firm cord-like body could be felt behind the cæcum over a point corresponding to the location of the appendix vermiformis. No tympanites or any other symptoms of peritonitis were present. I was satisfied of the existence of appendicitis from the history of the case and the symptoms and signs presented, and feared that during this or subsequent attacks perforation with all its uncertain consequences might take place. In view of the probability of such an occurrence, I advised a radical operation as the only means calculated to afford permanent relief. The patient had suffered so severely during the five preceding attacks that he readily consented to the proposed operation. During this attack he was confined to bed only at times, and took opiates as required for the pain. As the symptoms did not subside he was admitted into the Milwaukee Hospital April 30, for the purpose of having the appendix removed. A saline cathartic was administered the day before operation, and the following morning the colon was evacuated by a copious enema. The evening before operation the abdomen was shaved and thoroughly cleansed with warm water and potash soap, after which a compress wrung out of a sublimate solution 1:2000 was applied.

Operation May 1: Chloroform anæsthesia. After removal of the compress the surface was washed with undiluted alcohol. An incision about four inches in length was made directly over the center of the cæcum and parallel to the ascending colon, the lower angle of which reached to within an inch of Poupart's ligament. All hæmorrhage was carefully arrested before the abdominal cavity was opened. The peritoneum was divided between two anatomical forceps, when two fingers of the left hand were introduced and between them the opening was enlarged. Through this incision the cæcum came directly in view and presented a normal appearance both as to size and structure. No evidences of peritonitis or perityphlitis. On making pressure over the lower portion of the cæcum an elongated body about the thickness of an ordinary lead pencil could be distinctly felt rolling under the tip of the finger. The lower margin of the cæcum was grasped with the fingers, elevated, and brought into the wound. This manipulation brought into view the appendix which was directed upwards and inwards from its point of attachment, along the posterior wall of the cæcum. No adhesions between the appendix and the cæcum, but the mesentery of the appendix appeared to be shortened and exceedingly vascular. The peritoneal covering of the appendix appeared healthy, having retained its normal smoothness and lustre. The appendix was uniformly enlarged from its junction with

the cæcum to its distal extremity, and imparted a sensation of unusual hardness when grasped between the thumb and index finger. The mesentery of the appendix was ligated in several sections with fine silk and cut close to the appendix. The appendix was ligated near the cæcum with a silk ligature and amputated about a quarter of an inch below the point of ligation. The lumen of the appendix at the point of section was quite small, but as it was more than probable that it communicated with the cæcum, I deemed it necessary to prevent the possibility of a subsequent perforation from cutting through of the ligature by covering the stump with peritoneum. The stump was disinfected, dusted with iodoform, and buried by stitching the peritoneum from each side over it by a number of stitches of the continued suture. The cæcum was now returned and the wound closed by suturing the peritoneum with catgut, while the external sutures of silk were passed down to, but not through, the peritoneum. A compress of iodoform gauze and a thick layer of salicylated cotton retained by a number of strips of adhesive plaster encircling two-thirds of the body constituted the dressing. The subsequent history of the case was one of uninterrupted recovery. The pain disappeared as if by magic. The patient took no opiates after the operation. Temperature never above normal. On the third day the bowels were moved by a saline cathartic after which no further medication was necessary. At the end of a week the dressing was removed when the wound was found united throughout and the sutures were removed. At the end of the second week the patient left the hospital, and in the course of another week resumed his occupation. He is now in perfect health, has gained in flesh, and has been perfectly free from pain. The amputated appendix proved to be a very interesting pathological specimen. The part removed measured two inches in length, and in thickness corresponded in size to the last joint of the little finger. The lumen was uniform in size throughout and was large enough to admit a small-sized lead pencil. The appendix was slit open its whole length at a point opposite to the mesenteric attachment. On inspection of the mucous membrane lining it an oblong ulcer was discovered near the middle and opposite the mesenteric attachment. The ulcer measured about half an inch in length, and a quarter of an inch in width, its greater diameter corresponding to the long axis of the appendix. The margins of the ulcer were regular in outline and not undermined. It presented no evidences of repair. Its greatest depth corresponded to its centre. The whole mucous membrane was exceedingly vascular and much thickened, the submucous infiltration being uniform over its entire area. A transverse section of the appendix through the centre of the

ulcer, examined under the microscope, showed that the entire thickness of the mucous membrane and part of the muscular coat were destroyed by the ulcerative process, and that the remaining thickness of the wall as far as the peritoneum was infiltrated with embryonal cells and leucocytes which were closely grouped together in the connective tissue reticulum. The submucous tissue and part of the muscular coat were similarly infiltrated throughout. No fecal matter and no foreign body could be found in the lumen of the appendix, the whole contents consisted of a few drops of a highly viscid odorless secretion. The absence of any macroscopical cause of the inflammation, the condition of the mucous membrane, and the appearance of the ulcer substantiate the diagnosis of catarrhal appendicitis, which in this case had resulted in the formation of a catarrhal ulcer of considerable size and depth. There can be but little doubt that repeated acute exacerbations of the chronic inflammation would have finally resulted in perforation, and as the ulcer was located on the free side of the appendix there would have been great danger in such an event of invasion of the peritoneal cavity, and death from diffuse septic peritonitis. The second case came under the observation of Dr. Knut Hoegh, of Minneapolis, Minn., and through his courtesy I am permitted to incorporate it in this paper. It furnishes an illustration of another form of appendicitis (suppurative) amenable to early successful surgical treatment.

*Case 2.*—H. M., 37 years of age, merchant by occupation. For the last six or seven years he has suffered at intervals from attacks of pain in the abdomen. At first these attacks were not very severe, and of short duration, the general health remaining unimpaired. Questioned as to the condition of the bowels the patient stated that the attacks were usually attended by diarrhoea. The onset of pain was always sudden and apparently without any appreciable cause, as they often occurred during the night after the patient had retired the evening before in perfect health. In the beginning the attacks occurred about every six months, but later they came on more frequently, more severe, and of longer duration, and at the same time the general health became impaired. The later attacks he describes as commencing with a severe pain in the ileo-cæcal region which at times became excruciating, accompanied by sensations of chilliness. No vomiting, but more or less retching; bowels constipated; abdomen often distended and always tender on pressure over a limited space, at a point from which the pain always seemed to start.

Patient is not aware that he ever passed blood, mucus or pus with the stools. During the last fifteen months he has passed through five attacks.

the last one two months before the operation was performed. Since the last attack he has been unable to resume his business as he has suffered constantly from pain and tenderness in the ileo-cæcal region, loss of appetite, and an increasing debility. The patient looks prematurely old, showing evidences of senile marasmus seldom found in persons of his age. He is of medium height, somewhat emaciated, having lost twenty-five pounds of his customary weight. Examination of the abdomen revealed no tympanites and no swelling, but midway between umbilicus and the right anterior superior spine of the ilium a space about two inches square was found tender on pressure. Rectal exploration yielded a negative result. The usual internal treatment in such cases consisting of the administration of belladonna, nuxvomica, and alkaline cathartics was not followed by any material improvement, so that the patient readily consented to an operation which had for its object the removal of the appendix vermiformis which it was believed was in a condition of catarrhal inflammation. The absence of swelling and fever seemed to render it improbable that the symptoms were due to circumscribed peritonitis, or inflammation in the cæcal mesentery or para-cæcal connective tissue. The repeated attacks of pain, the localized tenderness, and the digestive disturbances pointed to a localized inflammation depending upon some chronic pathological change within or near the appendix vermiformis. Dr. Foster, of Minneapolis, saw the case in consultation with Dr. Hoegh, and concurred in the opinion that an operation should be performed. The writer was consulted by letter, and strongly urged the propriety of a speedy resort to surgical treatment. The operation was performed by Dr. Hoegh in the St. Barnabas Hospital, August 19, 1889, assisted by Drs. Foster and Wood. Chloroform was used as an anæsthetic. Operation performed under strict antiseptic precautions. Incision through right linea semilunaris. On opening the peritoneal cavity the appendix came at once in sight lying free in the peritoneal cavity, pointing towards the pelvis. It was about two inches in length, remarkably firm to the touch, and its serous surface quite vascular. At some points it had formed adhesions with the surrounding structures. The adhesions were separated and a ligature applied near its junction with the cæcum. The stump was buried in the same manner as in case 1. The cæcum showed nothing abnormal. It was noticed that the point of communication between the appendix and cæcum was very narrow, the lumen not exceeding the size of a knitting needle. The abdominal incision was closed in the usual manner. Soon after the operation the patient suffered considerably from nausea and retching which gave rise to considerable pain in the wound. A slight elevation in the tem-

perature a few days after the operation announced a slight suppuration in the superficial portion of the wound, which, however, soon subsided, and the healing by granulation proceeded in a satisfactory manner. Aside from this disturbance the patient went on to an uninterrupted and permanent recovery. Examination of the appendix after its removal showed that it was somewhat distended in its central part by a few drops of a thick, very offensive, purulent fluid of the consistency of cream, of a brownish color; the odor was not feculent, but rather fetid. No concretion or foreign body was found. The mucous lining of the appendix showed two distinct but not very deep ulcers, both involved the entire thickness of the mucous membrane. The ulcer nearest the cæcum was the largest occupying the whole circumference of the lumen about one-quarter of an inch wide. The second ulcer nearer the apex was not larger in circumference than the size of a split pea. The serous coat near the junction of the cæcum was considerably thickened. Microscopical examination of the fluid showed broken down tissue, pus corpuscles, and pigment granules.

#### GENERAL REMARKS ON EARLY RADICAL OPERATION FOR APPENDICITIS.

Excision of the appendix in cases as reported above must be considered in the light of a curative and prophylactic operation. It is curative, as by it the cause of the disease with the diseased tissues is completely removed, and it is prophylactic, as by it the disastrous consequences of a probable later perforation are positively prevented. Extirpation of the appendix at a time before the inflammatory process has reached the serous coat is one of the easiest and safest of all intra-abdominal operations. The operation is performed in a healthy aseptic peritoneal cavity, and if the customary antiseptic precautions are carried out healing of the visceral and abdominal wounds by primary intention may be confidently expected. The operation eliminates a structure which if not entirely useless has at most only an unimportant physiological importance.

#### INDICATIONS FOR OPERATION.

It may be stated as a general rule, to which there can be but few exceptions, that the appendix should be extirpated in all cases where from the symptoms and history of the case the existence of a localized destructive inflammatory process can be surmised. From a diagnostic and practical standpoint all cases of appendicitis can be divided into two classes: 1. Acute. 2. Chronic. There can be but little doubt that most, if not all, acute cases are preceded by a chronic lesion. The history of many cases, and the pathological conditions of numerous specimens corroborate this statement. A foreign body, for instance, may be present for a long

time without giving rise to serious symptoms, but it cannot remain for any length of time without causing a catarrhal inflammation and superficial ulceration. An ulcerative catarrhal inflammation may exist for a long time before it gives rise to acute symptoms, and when the acute attack makes its appearance the inflammation has reached the peritoneal surface and the connective tissue underlying the appendix and cæcum; it is then no longer an uncomplicated case of appendicitis as the primary inflammation has extended beyond the structures of the appendix, and has given rise to perityphlitis, with or without perforation. Chronic appendicitis is characterized by acute exacerbations of short duration, the attacks of greater or less severity occurring at intervals of a few months or weeks. Between the attacks the patient may be in perfect health, unless the attacks recur with great frequency, when impairment of the digestive functions produces general ill health. The most important symptoms which point to the existence of chronic appendicitis are localized pain and a circumscribed area of tenderness at a place corresponding to the location of the appendix. Simple appendicitis does not give rise to any appreciable swelling as long as the lumen of the appendix remains in communication with the cæcum, as the resistance of the indurated walls is sufficient to force the contents of the appendix into the cæcum. In persons with thin abdominal walls it is possible to feel the hardened and thickened appendix by making deep pressure while the patient is placed in a position that favors relaxation of the abdominal muscles. Tympanites is usually absent unless the appendicitis is complicated by circumscribed peritonitis. Rigidity of the abdominal muscles is absent as long as the inflammation is limited to the deeper structures of the appendix. During the acute exacerbations of the chronic form of the disease aside of the pain the general symptoms are not severe. The temperature is either normal or there is only a slight rise seldom above 100° F. The pulse is only slightly increased in frequency, and shows none of the characteristic features which it presents in peritonitis.

Vomiting is occasionally present, but is not a constant nor even a frequent symptom. Constipation which is usually present is probably more the result of a change in diet, rest, and the medicines taken for the relief of pain than the disease. The frequency of catarrhal and ulcerative inflammation in the interior of the appendix as compared with the remaining portion of the intestinal tract is probably owing to the anatomical location of this structure. The lumen of the appendix constitutes a cul-de-sac which is in communication with the intestinal canal, but which is virtually excluded from the fecal circulation, hence it serves an admirable purpose as a

reservoir for the collection, localization and retention of pathogenic microbes. That the anatomical location of the appendix acts as a predisposing cause in the etiology of localized forms of infection is evident from the course of the disease.

The inflammatory process remains limited and does not extend by continuity to the cæcum, the extension of the disease being only in a peripheral direction from the mucous membrane to the deeper structures. In conclusion it may be said that recurring attacks of pain in the region of the appendix with a circumscribed area of tenderness over the same point are presumptive evidences of the existence of appendicitis, and if the other symptoms and signs point in the same direction treatment by abdominal section is indicated.

#### TECHNIQUE OF OPERATION.

As an operation for simple appendicitis always presupposes an aseptic condition of the peritoneal cavity, it is of the utmost importance to secure by thorough antiseptic precautions an aseptic condition of everything that has to be brought in contact with the wound. The field of operation should be disinfected by shaving and thorough washing with warm water and potash soap, after which a moist compress saturated either with a 1-2000 solution of sublimate or a 2½ per cent. solution of carbolic acid is applied and allowed to remain from the time the disinfection is made the evening before the operation until the patient is ready for the operation the next day. Immediately before the incision is made, I am in the habit of washing the surface once more with one of the disinfectant solutions, and lastly with absolute alcohol. The instruments should be sterilized by boiling for ten or fifteen minutes immediately before the operation. The operator and assistants should disinfect their hands by washing thoroughly with warm water and potash soap, and subsequently a 1-1000 solution of sublimate. If everything has been rendered thoroughly aseptic, that is to be brought in contact with the wound, no antiseptic solutions will be necessary during the operation, unless perhaps for the disinfection of the stump after amputation of the appendix. Sterilized water is used for the sponges.

*Incision.*—The incision that renders the cæcum and appendix most accessible to inspection, examination and operative manipulation is one made parallel to the long axis of the ascending colon and cæcum. It should be about four inches in length and directly over the centre of the cæcum, and extend to within an inch of Poupart's ligament. With a sharp scalpel the skin, fascia and successive muscular layers are rapidly divided without the use of any director until the peritoneum is reached. At this stage a pause is made in the operation in order to arrest

hæmorrhage by applying hæmostatic forceps to every bleeding point, the forceps remain until the surgeon is ready to close the wound, when it will generally be found that ligatures are superfluous, as the compression and crushing of the tissues caused by the forceps have been sufficient to arrest the bleeding. By following this plan unnecessary ligation of small vessels is avoided. The peritoneum is picked up by two catch-toothed forceps, and between them the abdominal cavity is opened, and the incision subsequently enlarged to the desired extent between the index and middle finger of the left hand. As soon as the peritoneal cavity is opened the further steps of the operation will be greatly facilitated by packing around the cæcum a small compress of aseptic gauze wrung out of sterilized water for the purpose of preventing prolapse of the small intestines. If the appendix is below the cæcum it will come into sight at once, when it can be examined and directly dealt with. If, as is more frequently the case, it is behind and towards the inner side of the cæcum its size and direction can be readily ascertained by palpation through the cæcum, but to make it accessible to direct examination and operative treatment it is necessary to raise the lower margin of the cæcum.

*Excision of the Appendix.*—If the serous coat has not been implicated by the inflammation the only attachment to be separated is the mesentery of the appendix. This is always present, but varies greatly in length and width. If it is attached to the whole length of the appendix it should be ligated in several sections with fine silk ligatures as far as the cæcum. If inflammatory adhesions are present they are separated, and all bleeding points carefully tied. When the appendix has been thus completely isolated a ligature of fine silk is tied around its base close to the cæcum, and about a quarter of an inch below it the section is made with scissors.

*Treatment of Stump.*—As the interior of the appendix under such circumstances necessarily must always contain pathogenic microorganisms it is necessary to disinfect the cut surface of the stump thoroughly. This can be done with one of the disinfectant solutions, after which the stump should be dusted with iodoform. After amputating the appendix it has been heretofore customary to drop the stump without making any provision against the possibility of perforation, subsequently taking place at the point of ligation. This I consider a great mistake. The ligature approximates a diseased mucous membrane, and if after the operation the entire stump is not speedily surrounded by a wall of impermeable granulation tissue which is later transformed into a connective tissue capsule, there is great danger that perforation will take place after cutting through of the ligature, thus exposing the patient to the same danger he was in before

the operation. To obviate the possibility of such an occurrence the stump, after thorough disinfection and iodoformization should be covered with peritoneum by stitching the serous surfaces of the cæcum from both sides over it by a number of Lembert sutures. The serous surfaces will become agglutinated in a few hours, and in a few days the adhesions will have become sufficiently firm to protect the surrounding tissues and the peritoneal cavity against extravasation should leakage take place at the point of ligation. By resorting to this precaution we protect the patient against all possibility of the occurrence of perforative peritonitis subsequently, as the perforation, should it occur, of necessity would take place into the cæcum.

*Closure of Abdominal Incision.*—More care is required in closing an incision made through the several muscular layers of the abdominal wall than by going through the median line, as the ordinary way of closing a median incision would be very likely to be followed by a ventral hernia. The peritoneum must be sutured separately with fine catgut or silk sutures, while the remaining sutures are passed down to, but not through, the peritoneum. No provision for drainage is necessary in these cases.

*Dressing of Wound.*—After dusting the wound with iodoform a narrow strip of protective silk is applied over it, when it is covered with a compress of iodoform gauze and a larger compress of salicylated cotton which are retained with a few broad strips of rubber adhesive plaster encircling two-thirds of the body. After this the whole abdomen is enveloped with a thick layer of common cotton over which a well-fitting binder is snugly pinned; this not only gives additional support to the wound, but furnishes likewise an agreeable and efficient support to the abdominal wall.

*After Treatment.*—As it is advisable to move the bowels the day before the operation by a saline cathartic, and to empty the colon by enema the following morning, the bowels should not be disturbed again for several days after the operation. This can be accomplished by administering several ten-drop doses of deodorized tincture of opium, and placing the patient on absolute diet for at least two or three days. On the third day a saline cathartic is administered, and, if necessary, this is followed by an enema. The sutures are removed at the end of the first week, but the patient is not allowed to leave the bed for another week for fear that the adhesions might yield and a hernia might follow. For several weeks after this he should wear some kind of an efficient abdominal support to guard still longer against the same accidents.

#### CONCLUSIONS.

1. All cases of catarrhal and ulcerative ap

pendicitis should be treated by laparotomy and excision of the appendix as soon as the lesion can be recognized.

2. Excision of the appendix in cases of simple uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations.

3. Excision of the appendix in cases of appendicitis before perforation has occurred is both a curative and prophylactic measure.

4. The most constant and reliable symptom indicating the existence of appendicitis are recurring pains and circumscribed tenderness in the region of the appendix.

5. All operations on the appendix should be done through a straight incision parallel to and directly over the cæcum.

6. The stump after excision of the appendix should be carefully disinfected, iodoformized, and covered with peritoneum by suturing the serous surface of the cæcum on each side over it with a number of Lembert stitches.

7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound.

8. Drainage in such cases is unnecessary and should be dispensed with.

## MEDICAL PROGRESS.

**HYDATID CYST OF THE LIVER. RUPTURE—RECOVERY.**—DR. H. C. MARKHAM, of Independence, Iowa (*North American Practitioner*, October, 1889) reports a case of this description. The cyst was first discovered three years ago. Under rest and alterative treatment amelioration of the symptoms apparently took place. In December last the patient's condition became much worse. The tumor, which appeared at the inferior border of the lower ribs, anteriorly, was now tense and as large as a pint bowl. A diagnosis of hydatid cyst was ventured at this time. A specimen of the cystic contents was obtained with a hypodermic needle, a subsequent examination of which confirmed the diagnosis. Upon the withdrawal of the needle the patient experienced excruciating pain and gave signs of collapse; the tumor meanwhile had disappeared, having evidently ruptured. The cyst refilled and soon reached the size of a fetal head at term. It was aspirated and 3 pints of turbid serum removed, after which a strong solution of iodine was injected and allowed to remain for some time. An apparent cure was thus effected. At present deep palpation detects the hardened residue of the sac.

**GALACTOCETE TESTIS.**—A case is reported from the clinic of DR. A. B. MILES, New Orleans,

which, for want of a better term, is indicated by this title. The testicle had been swelling for three months at the time of the examination. With the hypodermic needle a small quantity of a milky-looking fluid was drawn off. Examined in the pathological department of the Charity Hospital it was found to contain numerous fine granules in a state of active movement. No bacteria were present. Five hours later the testicle was found to be greatly diminished in size and within twenty-four hours the patient was discharged apparently cured. Five days later there was no evidence of a return of the former symptoms.—*N. O. Med. and Surg. Journ.*, Sept., 1889.

**THE RELATIONS OF GROWTH OF THE BODY TO ITS ORGANS.**—From an analysis of a large number of observations made in the Pathological Institute of Munich, K. OPPENHEIMER makes the following deductions:

1. The bodily weight reaches its highest relative standing earlier in females than in males. The weight of the adult man is about twenty times as great as at birth; that of the adult woman eighteen times as great. The length of the body reaches its highest relative point in man at the age of 15 years, when it amounts to 158 cm.; in woman the highest relative point is reached at the same age and amounts to 153.6 cm.

2. The growth of the lungs surpasses that of the body as a whole at nearly all periods, and especially at the middle period of growth.

3. The heart increases approximately in proportion to the entire body.

4. The spleen and kidneys increase proportionately with the heart.

5. The liver and notably the brain do not develop proportionately with the body.

6. The relative lack of development in the liver and brain is compensated by the rapid relative increase of fat and muscle, particularly the latter.

**INCOMPLETE ABORTIONS.**—DR. A. B. CARPENTER, of Cleveland (*Cleveland Med. Gaz.*), is strongly opposed to the expectant treatment of these cases, as he finds in it very grave sources of danger to the patient. Such cases require, on the contrary, prompt and radical treatment, whereby the retained products of conception are removed manually or otherwise. He finds the manual method unsatisfactory, and is disposed to adopt the method of Martin, of Berlin, who anesthetizes his patients and cures and douches the uterus with antiseptic precautions, completing the operation by applying tincture of iodine to the endometrium by means of the uterine syringe. In the after-treatment Dr. Carpenter avoids the use of opiates, but employs antipyrin with advantage.

CRIME AND INSANITY.

The universal testimony of all who have paid attention to the subject, is that insanity is incomparably more frequent among the inmates of prisons than in the general population. While one insane person to three hundred would be considered a large proportion of insane in a community, careful observers have found from 3 to 5 per cent. of prisoners to be either insane or imbecile. Such a state of affairs can only be accounted for on the supposition that very many convicts are either insane or strongly predisposed to insanity at the time of their conviction, or that there is something in the influence of prison life specially favorable to the development of mental derangement. Doubtless all of these elements contribute to the result. Frequently as the plea of insanity has been abused to defeat the ends of justice, there can, unfortunately, be no doubt that it is far from being a rare occurrence for persons to be sentenced as criminals who were, at the time of the commission of the unlawful act, influenced by insane delusions, actuated by morbid impulses, or incapable, by reason of mental enfeeblement of appreciating the true nature and results of their actions. The mistakes of juries in this respect are numerous, and the interpretation of the law, in this country and Great Britain, has been such that many persons whose mental unsoundness was recognized and admitted, have still been held legally responsible for the results of their disease. In a still larger proportion of cases, probably, although no dis-

tinctly morbid symptoms had been noticed before the commission of crime, there was such a predisposition to mental disease as rendered its development certain under favoring conditions. It is well known that habitual criminals are, as a class, not only uneducated, but of a low order of intellect, and incapable of any high degree of mental development. Defects of physical development, such as are frequent among the insane and idiotic, are so common in criminals that LOMBROSO and his followers maintain that habitual criminality is a disease, capable of physical diagnosis, and equivalent to moral insanity. We do not believe that this view is correct, as it certainly is not indorsed by most of those who have made a study of the subject, but although we believe it a mistake to elevate criminality to the rank of a distinct disease, there can be no reasonable doubt that it is often the result of an abnormal organization.

Making all reasonable allowance for these factors, it must, we fear be admitted that the influences of prison life are, in many cases, calculated to develop tendencies to mental disease which might, under more favorable circumstances, lie dormant. This is, probably, to a certain extent, unavoidable. The sense of disgrace, the loss of liberty, the injury as regards prospects for the future, are depressing influences which might be sufficient, of themselves, to unbalance a brain already predisposed to disease. In many cases, however, even in what are considered well-managed prisons, there are influences at work, in the monotony of the life and the lack of healthy occupations for the mind, to say nothing of the frequently unwholesome conditions as regards light, ventilation and food, which are needlessly unfavorable to the preservation of mental soundness. To discuss the general subject of prison administration would not be in place here, but it need hardly be said that in so far as a system, or lack of system, favors the development of insanity, it is neither humane, just, nor economical.

Judging from the experience of the past, it is scarcely to be expected that any efforts for a more scientific and humane interpretation of the law in reference to the insane accused of crime will meet with immediate success. The prospect in regard to prison reform is perhaps more encouraging. The law passed at the last session of the New York legislature, providing for an extension to

all the prisons of the State of the system of grading convicts according to their conduct, furnishing regular instruction and allowing suitable cases liberty on parole, which has worked so satisfactorily at the Elmira Reformatory, must be considered a long step in advance, and can hardly fail to find imitators elsewhere. By rendering the conditions of prison life more healthy, and less hopeless, it is reasonable to expect that it will materially reduce the number of those becoming insane during their confinement. The proportion of insane among convicts will, however, doubtless continue to be large, and the question of their treatment is one in which our profession should feel an interest and might reasonably hope to exert an influence.

In most of the States of this country, so far as we are aware, insane convicts receive very little treatment appropriate to their condition. If it is impracticable or unsafe to work them with other prisoners, they are generally confined in solitary cells, and no systematic attempt is made to divert their minds from their morbid ideas by recreation or employment. The natural result is that cases which might recover under suitable management drift on into hopeless dementia. At the expiration of their term of imprisonment they are sent to swell the multitude of hopeless chronic cases which crowd the wards of public asylums. Their presence there is objectionable in many ways. Although many of them are as inoffensive as most of those with whom they are brought in contact, there is always a considerable proportion in whom moral degradation is more conspicuous than intellectual impairment, and who, by their violence, insubordination, and continual attempts to escape, exercise a constant disturbing influence. Even when not personally objectionable, their presence is often felt as a degradation by such of their fellow-patients as are capable of being influenced by such feelings.

In addition to discharged convicts, nearly all State asylums contain more or less patients who have escaped trial or conviction for crime on the ground of insanity, to whom the same objections apply. In some such cases insanity has been feigned in order to escape the just penalty of wrong-doing, and it is frequently the case that it is not so well marked as to satisfy the public sentiment as to the innocence of the accused. Escapes under such circumstances are particu-

larly unfortunate, and we have reason to think they are not very infrequent. The organization and discipline required by this class are different from those best adapted to the treatment of the great bulk of the insane, and to the attempt to treat both classes together is not calculated to promote the best interests of either.

The solution of the difficulty lies, unquestionably, in the provision of separate institutions for the treatment of this class. Of these there are already two in this country, in New York and Michigan, and the Legislature of Vermont, at its last session, provided, in the act establishing a State asylum, that detached wards should be built for the accommodation of the criminal insane. The experience of the institutions already in operation has shown the advantages of this plan both to the insane convicts and the population of the other asylums. Such institutions should be constructed and administered with prime regard to security, which need not be inconsistent with a very considerable degree of liberty and comfort to a large proportion of the inmates. They should receive all insane convicts as soon as their malady becomes evident, that they may have the benefit of early treatment. In case of recovery, they should be returned to prison to serve out the unexpired portions of their sentences. Persons accused of felony and found to be insane should also be committed to these institutions; and it might be well to provide, as has been done in Michigan, for the removal to them, from the other asylums, of those patients who, by persistent homicidal propensities, are a constant menace to the safety of their fellows. Each of our more populous States has enough insane of these classes to justify the erection of a separate institution for their care, and there are few in which the existing asylums are not already so crowded as to make additional accommodation necessary.

In Arkansas additional room is needed for the insane, and the superintendents of the asylums and the State Board of Charities unite in recommending the erection of a separate institution for this class. It is to be hoped, in the interest of all concerned, that the Legislature will take prompt action on this subject at its next session.

## THE RADICAL TREATMENT OF SPINA BIFIDA.

Considerable attention is being directed, of late, to the treatment of spina bifida (*id est*, hydrorrhachis) by means of excision of the sac of the tumor. This is distinctly a reversion to first principles, inasmuch as the operation is by no means a new one, and has for many years past been discountenanced by the authorities as unproductive of the best results. But, like many another surgical procedure that has long since been laid away on the shelf, it bids fair to be freed from its venerable dust and appear again with new lustre. There are times, no doubt, when we all wish we were surgeons to take our part in the mighty innovations of modern surgery which are so rapidly removing the opprobria of our art; but whether we are surgeons or not, we take a just pride in the promotion of medical science, and hail with pleasure every advancement made in the direction of saving life and promoting human welfare.

Many years ago the surgeons felt obliged to abandon the radical operation for the relief of hydrorrhachis as altogether too dangerous and too barren of good results; indeed, most of our authoritative writers on surgery and obstetrics are still outspoken in their condemnation of such an operation, and as late as 1885 a committee appointed by the *Clinical Society of London* reported unfavorably upon the radical operation and approved of the treatment by iodine injections as the one most nearly imitating the process of natural cure and, therefore, most widely applicable. Nevertheless a sufficiently large number of successes obtained by the radical method have been recorded to raise a reasonable hope that a very decided improvement may be obtained by returning to the older plan of treatment. The treatment by iodine injections, which was popularized by the results secured in the hands of Brainard, Velpeau, Morton, Watt, Eate, Ewart and others, is, at best, unproductive of very satisfactory results. Thus, BRAINARD obtained a permanent cure in three cases out of seven, and VELPEAU in five out of ten. On the other hand, ROBSON, of Leeds, reports successful results in three of four cases operated upon by excision, while other and similar results are reported by Wilson, Atkinson, Howson and Barton, of England, and by Hayes and Hurd, of our own country. The latter, DR. H. P. HURD (*Theor. Gaz.*, Oct. 15, 1889), in describing his own case, has also reviewed the lit-

erature of the subject. As Dr. Hurd's citations of cases are mostly from English sources, it is with pleasure that we direct attention to four other cases which have recently been given publicity in Chicago, DR. A. E. HOADLEY having reported a successful case to the Chicago Medical Society (Oct. 7, 1889), and DR. CHAS. T. PARKES having reported to the Chicago Gynecological Society (Oct. 18, 1889) three cases operated on, with two successful results. Although such cases as these are not yet sufficiently numerous to enable one to predicate definite conclusions, they have at least subserved excellent purposes in proving that the radical method, in proper hands, is capable of yielding satisfaction. Furthermore, the testimony of these operators seems to indicate three pretty clearly defined facts:

1. That the escape of a considerable quantity of fluid from the sac is not necessarily attended by dangerous sequelæ.
2. That there is less danger from injury to the nerve structures than has been believed, and
3. That many of the unfavorable results of former operations were, doubtless, due to lack of proper precautions relative to the prevention of sepsis.

## EDITORIAL NOTES.

## HOME.

THE first medical degree ever given to an American woman was given forty years ago. To-day there are 2,500 women in this country having diplomas from either American or foreign schools.

YELLOW FEVER IN FLORIDA.—Surgeon-General Hamilton, of the Marine-Hospital Service, has received a telegram from Dr. Porter, at Key West, reporting another case of yellow fever at that place, and that quarantine restrictions have been resumed. The patient in this case is E. Ellinger, who left Havana September 21, bound for New York.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its annual session at Nashville, Tenn., November 12, 13 and 14, 1889. The following are the papers to be read: The President's Annual Address, Dr. Hunter McGuire, Richmond, Va.; "Report of Gynecological Work, with Especial Reference to Methods," Dr. R. B. Maury, Memphis, Tenn.; "Direct Herniotomy, with Cases," Dr. W. O. Roberts, Louis-

ville, Ky.; "Open Abdominal Treatment" Dr. B. E. Hadra, Galveston, Tex.; "The Abortive Treatment of Acute Pelvic Inflammation," Dr. Virgil O. Hardon, Atlanta, Ga.; "The Importance of Early Treatment of Inflammatory Affections of the Uterus," Dr. Wm. C. Dabney, University of Virginia; "The Relation of the Nerve System to Reparative Surgery," Dr. Thos. O. Summers, Jacksonville, Fla.; "Concerning the Causes of Frequent Failure of Relief of Reflex Symptoms after Trachelorrhaphy," Dr. W. F. Hyer, Meridian, Miss.; "Cranial Surgery," Dr. DeSaussure Ford, Augusta, Ga.; "The Treatment of Ectopic Pregnancy," Dr. W. H. Wathen, Louisville, Ky.; "Laparotomy in Extra-Uterine Pregnancy," Dr. Waldo Briggs, St. Louis, Mo.; "Epithelioma of the Penis," with the Report of a Case," Dr. D. W. Yandell, Louisville, Ky.; "Laparotomy in Intestinal Obstruction," Dr. C. Kollock, Cheraw, S.C.; "An Experimental Study of Intestinal Anastomosis," Dr. Jno. D. S. Davis, Birmingham, Ala.; "Operative Interference in Ascites," Dr. Hugh M. Taylor, Richmond, Va.; "Observations Pertaining to Pregnancy and Parturition," Dr. W. Duncan, Savannah, Ga.; "Puerperal Convulsions," Dr. Jno. Herbert Claiborne, Petersburg, Va.; "Some Remarks Upon Aneurisms, Relating More Especially to their Surgical Treatment," Dr. F. T. Meriwether, Asheville, N. C.; "Coccygodynia and Its Treatment," Dr. Hunter P. Cooper, Atlanta, Ga.; "The Improved Cæsarean Section *vs.* Craniotomy," Dr. W. D. Haggard, Nashville, Tenn.; "Conservative Surgery in Injuries of the Foot," Dr. J. T. Wilson, Sherman, Texas; "Gun-Shot Fractures of the Femur," Dr. Jno. Brownrigg, Columbus, Miss.; "Tropho-Neurosis as a Factor in the Phenomena of Syphilis," Dr. G. Frank Lydston, Chicago, Ill.; "Trophic Changes Following Nerve Injury in Fractures, with report of two cases," Dr. Wm. Perrin Nicolson, Atlanta, Ga.; "Treatment of Malignant Diseases of the Rectum," Dr. W. T. Briggs, Nashville, Tenn.; "Gynecology in its Relations to Obstetrics," Dr. W. L. Robinson, Danville, Va.; "Observations Based Upon an Experience of Seventy-five Abdominal Operations," Dr. Jos. Taber Johnson, Washington, D. C.; "Twenty Consecutive Cases of Abdominal Section," Dr. L. S. McMurtry, Danville, Ky.; "Triple Amputations," Dr. J. B. Luckie, Birmingham, Ala.; "The Treatment of Contracted Bladder by Hot Water Dilatation," Dr. I. S.

Stone, Lincoln, Va.; "Complications Occurring in the Clinical History of Ovarian Tumors," Dr. Richard Douglas, Nashville, Tenn.; "What Kind of Instruments Does Modern Antiseptic Surgery Demand?" Dr. J. W. Long, Randleman, N. C.; "Intestinal Anastomotic Operations with Segmented Rubber Rings, with Some Practical Suggestions as to Their Use in Other Surgical Procedures," Dr. A. V. L. Brokaw, St. Louis, Mo.; "Leucocythæmic Tumors as a Neoplastic Exponent of Rheumatism and Their Similarity to Malignancy—with a Case," Dr. W. Locke Chew, Birmingham, Ala.; "What Civilization is Doing for the Human Female," Dr. A. Laphorn Smith, Montreal, Canada; "The Achievements of Modern Surgery," Dr. J. Ewing Mears, Philadelphia, Pa.; "The Treatment of the Pedicle in Suprapubic Hysterectomy," Dr. Wm. M. Polk, New York; "Pus in the Pelvis and How to Deal with it," Dr. Joseph Price, Philadelphia, Pa.

Members of the profession are invited to attend.

EXTENT OF THE OPIUM TRAFFIC.—The Massachusetts Board of Health has been making a series of investigations for the purpose of learning the extent of the opium traffic in that State. The result shows that while the use of the drug is not rapidly increasing it yet has a strong hold among all classes. Circulars were sent to the druggists and older physicians. Among the inquiries and replies are these:

1. From your own observation is the use of opium and its preparations increasing in the community in which you live? Two hundred and twenty-five answers received; 66 per cent. replied no, 28 per cent yes, 6 per cent. do not know.

2. If such be the case, what is the probable cause of such increase? Twenty per cent. give the use of opium by physicians as the sole cause, 11 per cent. give this as the cause in part. Ease of obtaining opium from druggists, excessive brain work, desire for stimulation, fast living, comprise most of the remaining answers.

3. Are diseases calling for the use of opium increasing? Two hundred and nine answers; 84 per cent. no, 16 per cent. yes.

4. In what form or manner is it employed? One hundred and sixty answers; 30 per cent. all forms, 22 per cent. morphia, 13 per cent. morphine and laudanum, 10 per cent. morphia by the mouth and hypodermically, 10 per cent. morphia hypodermically.

5. Does the prohibition of alcohol increase its (opium) use? Two hundred and two answers; 67 per cent. no, 10 per cent. yes, 3 per cent. possibly, 20 per cent. do not know.

6. What classes of people mostly use it? One hundred

and sixty-six answers; 30 per cent. all classes, 22 per cent. higher, 8 per cent. middle, 6 per cent. lower, 12 per cent. middle and higher, 14 per cent. nervous women, 8 per cent. do not know.

**THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.**—The Board of Trustees, in recognition of distinguished services rendered the institution, as former Professors, have elected Richard Levis, M.D., Emeritus Professor of Surgery; J. Solis-Cohen, M.D., Emeritus Professor of Laryngology; Charles H. Burnett, M.D., Emeritus Professor of Otolaryngology; and Charles B. Nancrede, M.D., who was recently called to the Chair of Surgery in the University of Michigan, Emeritus Professor of General Orthopædic Surgery.

An additional Chair of Orthopædic Surgery was created and Thomas G. Morton was elected Professor. Professor Morton will utilize the vast clinics of the Orthopædic Hospital and Infirmary for nervous diseases, Professor S. Weir Mitchell having for some time past used the Nervous Department.

A new Department of Dentistry was created and the Faculty was authorized to place a competent teacher in charge until the next meeting of the Trustees.

A new Department of Experimental Therapeutics and Physiology was created, and Thomas J. Mays, M.D., was elected Professor.

The Chair of Clinical Surgery was filled by the election of Thomas S. K. Morton, M.D., Professor.

C. L. Bower, M.D., was elected Adjunct Professor of Clinical and Operative Surgery, and J. Abbott Cantrell, M.D., Adjunct Professor of Diseases of the Skin.

The Chair of Pathology was left vacant until the next meeting.

The report of the Building Committee was read, in which it was stated that contracts had been signed for preliminary work to the amount of \$23,150. About \$30,000 will be required to finish the building, and it was decided to push the building to completion as fast as the donations for the purpose could be obtained. The overcrowded condition of the present building makes it necessary to use every exertion to move into the new building in the early spring, even though it be unfinished.

REMBRANDT'S "LESSON IN ANATOMY."—Rem-

brandt's celebrated picture entitled "A Lesson in Anatomy," a full size copy of which hangs at present in the hall of the College of Physicians of Philadelphia, has, we understand, been purchased by Mr. Ellesworth, for the Institute of Art, of Chicago. It formerly belonged to the Princess de Sagan, and until recently has been in an art gallery in the Hague.

**THE RED CROSS AT JOHNSTOWN.**—Miss Clara Barton has communicated to one of the Johnstown newspapers the decision of the Red Cross Association to bring to an end the relief campaign in the Conemaugh valley. The present organization will be disbanded to give place to a lesser relief administration, under local control, which will receive from Miss Barton all supplies that remain undispensed when she departs. This has been the most exacting campaign through which the American Red Cross Society has been called to pass; the records show that over 30,000 reliefs, medical and other, have been granted during the past four months.

#### FOREIGN.

**DR. PHILIPPE RICORD**, the celebrated French surgeon, is dead. He was born in Baltimore, Md., December 10, 1800.

**GERMAN STUDENTS' DUELS.**—The *British Medical Journal* says that two students, one belonging to the medical and the other to the legal faculty of the University of Halle, have recently been condemned to three months' imprisonment in a fortress for fighting a duel with pistols, although neither of them was hurt. It appears from this that a paternal Government will only allow bellicose *Burschen* to avenge their honor by slashing each other's faces.

**DR. P. MÉNIÈRE** has resigned the management of the *Gazette de Gynécologie*, published in Paris, France, on account of ill-health. Dr. Phillippeau is his successor.

**BRITISH MEDICAL ASSOCIATION.**—It is probable that the 1891 meeting of the Association will be held in the ancient city of Bristol, the metropolis of the West of England, a city noted for its historic buildings and romantic surroundings.

**PRESIDENT DE WINTON**, of the geographical section of the British Association, states that American climate has improved the physique of the Anglo-Saxon race.

## TOPICS OF THE WEEK.

## THE ACIDS OF THE STOMACH.

There is no doubt that the chief acid found in the stomach during natural digestion is free hydrochloric acid. This has been abundantly proved by Bidder and Schmidt, and numerous observers succeeding them. The methods used are, however, too long and too complicated to employ in clinical work. The physician wishes to know what, in a particular case of disease, are the chemical changes going on in the stomach: whether, for example, hydrochloric acid is present as well as pepsin and organic acids. Now, in the examination of the contents of a diseased stomach three forms of acid may be present—hydrochloric acid, a mineral acid; organic acids, such as lactic acid, butyric, etc.; and thirdly, acid phosphates. It is chiefly of importance to determine the presence of hydrochloric acid and of organic acids. Many methods have been proposed for doing this; they consist mainly in testing the effect of the stomach contents on various colored solutions. Thus a solution of methyl-violet is decolorized by hydrochloric acid, so that if this reaction is obtained the free acid is present in the liquid tested. Lactic acid turns the violet a dirty yellow. Tropæolin also is turned deep reddish-brown by free hydrochloric acid. Unfortunately these tests, simple as they appear, are not accurate, since the reactions are interfered with by the presence of peptones and of some neutral salts, and, as these are usually present in the stomach contents, no reliable results can be obtained by using methyl-violet and tropæolin. They have been superseded by congo-red, which is turned blue by free hydrochloric acid, and by a solution of vanillin and phloroglucin in alcohol, which is turned a deep red by the same acid. These simple clinical tests are, however, rendered useless by the fact that they are interfered with by the presence of peptone, ammonium salts, chlorides, and phosphates.

In the present state of our knowledge, therefore, there is no reliable indicator for the presence of free hydrochloric acid in the stomach contents. Other methods which may be used are too complicated for clinical use. Thus ether has the property of dissolving organic acids from a liquid, leaving the mineral acids in solution. It may thus be used for separating the lactic, butyric, and other acids from the hydrochloric acid; and if in a liquid obtained from the stomach it is found that ether removes the whole of the acids present, it may be concluded that no free hydrochloric acid is present. In many cases this conclusion would be an important one as a clear indication for a line of treatment. Dr. Leo has lately<sup>1</sup> published a new method for the indication of free hydrochloric acid which may prove useful. Leo considers the case where it is only a question of the presence of free hydric chloride, and of an acid phosphate. To a few drops of the stomach contents a pinch of carbonate of calcium is added; if the acidity, as tested by litmus paper, disappears, only a free acid is present, but if the liquid is still acid after the addition of the chalk, an acid

salt is present. If, moreover, organic acids be present, they must be first removed by shaking with ether before the chalk is added. It does not seem that Leo's method is one that can be applied at the bedside, because the detection of free hydrochloric acid is chiefly requisite in those cases in which organic acids are also present, as in cases of dilated stomach. At present, indeed, a ready method, suitable in clinical practice for the detection of free hydrochloric acid in organic liquids is a desideratum. —*British Medical Journal*.

## PROFESSOR CHARCOT.

It would seem almost superfluous to say anything of Dr. Charcot, as he is already so well known in the profession. He is certainly one of the most remarkable medical characters of the day, and even physically his person and features bear a peculiar stamp. He is a man of ordinary stature, 55 years of age, and stoops a little. His face is pale and clean-shaven, resembling very much that of the first Napoleon, and giving the impression of a thoughtful mind. After having for a long time devoted himself to the study of pure pathological anatomy, he gave himself up to the clinical study of nervous affections, a scientific territory till then almost unexplored. He here displayed rare qualities of observation, an exemplary patience, a marvelous prudence, and the most perfect method. He has won the intellectual esteem of his bitterest opponents, a world-wide reputation, and the assurance of having attached his name to a work which will remain imperishable. Prof. Charcot's clinic at the Salpêtrière is well known, and constitutes the greatest scientific centre in France for the study of the pathology, diagnosis and treatment of nervous diseases. It is attended by physicians and students from all parts of the world, where they find a vast amount of clinical material and the complete methods of study organized and developed by the eminent professor, aided by a body of distinguished pupils and assistants who surround him in his daily visits. For many years Prof. Charcot has taken a foremost place among the leaders of medical science; his clinique, his laboratories, his works and his pupils constitute one of the chief glories of the faculties of Paris. His lectures are most impressive; he is sober in manner, clear in diction, picturesque in illustration, original in conception, indefatigable in research, and spares neither time, labor nor wealth in using all the methods of clinical illustration at his disposal. It would be fastidious and useless to analyze here all his discoveries; I would simply refer to some which leave the narrow limits of medicine and touch somewhat on philosophy. In the chaos of the notions acquired on cerebral function it can not be denied that it was Charcot who was the first to throw light on the subject, in finding, as if by a stroke of genius, the method which permitted him to fix the cerebral motor localizations. He, at the same time with Kussmaul, taught men the mechanism of their memory and of their language. And who does not remember the debates on the questions of magnetism and of hysteria that have so recently taken place among the lay and medical public? It was Dr. Charcot who, armed with his scientific *sangfroid* and method, reduced to definite

laws facts which, in appearance, were the most incoherent. I may here observe that to the Hospice of the Salpêtrière, which was originally intended only for the aged and insane of the female sex, there being 3,145 of the former and 720 of the latter, there have been added forty-two beds for male patients and a certain number of female patients suffering from nervous diseases, which additions were made for the most special study of diseases of the nervous system. It may be said that Dr. Charcot began his professional career at that asylum. He was interne in it in 1852, and became physician in 1862. He was appointed professor of diseases of the nervous system in 1881, a chair which was created for him. Since 1862 he has not ceased to give his memorable series of lectures and clinical conferences, which are held every Tuesday morning at the Salpêtrière, and on Friday morning he holds consultations, both of which are always well attended. In addition to the above there are thirty beds for children afflicted with nervous diseases, and 200 beds for epileptics. Besides these he has the control of a series of infirmary wards, into which are brought all the patients whom he desires to select from among the infirm women who are the permanent inmates of the other parts of the Salpêtrière. Altogether he has at his disposal for clinical study and under direct treatment more than 2,000 patients. No wonder, then, that with this vast experience Prof. Charcot should be regarded as the highest authority on nervous affections. He is also a member of the Academy of Medicine.—Paris Correspondence, *Boston Med. and Surg. Journal*.

WHAT REAL VALUE HAVE THE NATURAL MINERAL  
WATERS IN THE TREATMENT OF DISEASES  
OF THE SKIN?

At the recent meeting of the American Dermatological Association DR. L. D. BULKLEY, of New York, presented a paper in which he discussed the subject of natural mineral waters in the treatment of disease, and from which we make the following extract:

It is the popular impression that natural mineral waters help certain skin diseases; that some are to be applied on the outside, and some are to be taken internally for the purpose of washing out the noxious agent. No doubt many cases are benefited, but any one who has seen many cases of the effects of natural mineral waters must be many times disappointed. The water is but one element in the case; hope and faith may play an important part. Then there is the change of scene, rest from ordinary occupation, and, perhaps, the enforcement of regular hours.

In Europe, most of the springs have resident medical advisers, but, unfortunately, there are few of them in this country. It should be remembered that in certain instances other appropriate remedies are being taken at the same time; witness the treatment of syphilis at the hot springs of Arkansas. But in any case it is the water, pure and simple, which contributes most to the cure. Most of the waters have little effect upon the skin, but reach especially the kidneys, liver, bowels, etc. We cannot always predict the effect of the water from its chemical analysis. Certain mineral waters are taken hot at

the springs, but cold, or even in ice, when at a distance. In the case of iron, arsenic and bromine springs, the results are rather indefinite. Sometimes cutaneous diseases depending on debility will be improved. We have all seen cases of eczema which have been treated at the sulphur springs in vain. Where there is a rheumatic element back of the cutaneous lesion, no doubt some good can be received; but in those cases it is the alkaline water, and not the sulphur, which is of benefit.

Like all other remedies, the use of springs must be carefully prescribed in order to be of the greatest use. Probably more benefit is derived in eczema than in other diseases, and even then it should be toward the close of the case. First, should be used the alkaline and moderately purgative waters, and then a tonic course. Carlsbad is advisable where there is a large abdominal plethora. In acute cases the hot springs should be used. Care must be taken lest acute eczema be excited by the springs, for some very severe cases have been lighted up in this manner. In psoriasis, sometimes sea-bathing is of far more benefit than the mineral springs. In syphilis, little benefit follows unless other treatment is kept up. Acne will sometimes be benefited somewhat, and the iron springs are better than the sulphur. The chief difficulty in the use of this treatment is the fact that these patients are not under supervision, and are apt to follow their own fancy or the guidance of the attendants at the baths.

INJURIES BY RAILROAD.

Railroad business and travel is a topic that is absorbing increased attention every year, and new guards against danger are being constantly applied. A monster petition, containing nearly 10,000 names of brakemen, has lately been sent to the Interstate Commerce Commission, asking them to urge upon Congress the necessity for legislation requiring the use of automatic brakes and couplers on freight cars; and when it is remembered that something like 450 men are killed, and 4,000 injured every year in operating freight cars, the subject assumes great importance. An article in *Scribner's Magazine* for September gives the following facts on the general topic of safety in railroad travel:

When one reflects upon the destructive energy which is contained in a swiftly moving train, and sees its effects in a wreck; when he understands how many minute mechanical details, and how many minds and hands must work together in harmony to insure its safe arrival at its destination, he must marvel at the safety of railroad travel. In the year 1887, the passengers killed in train accidents in the United States were 207; those injured were 916. The employes killed were 406, and injured 890. These were in train accidents only, it must be remembered, and do not include persons killed at crossings, or while trespassing on the track, or employes killed and injured making up trains. As will be seen later, the casualties in these two classes are much greater than those from train accidents. The total passenger movement in 1887 was equal to one passenger traveling 10,570,306,710 miles. That is to say, a passenger might have traveled 51,000,000 miles before being killed, or 12,000,000 miles before being injured. Or he might travel day and night steadily at the rate of 30 miles an hour for 194 years before being killed. Mark Twain would doubtless conclude from this that traveling by rail is much the safest profession that a man could adopt. It is unquestionably true that it is safer than traveling by coach or on horseback, and probably it is safer than any other method of getting over the earth's surface that man has yet contrived, unless it may be by ocean steamer. If one wants anything safer, he must walk.

## PRACTICAL NOTES.

### EXALGINE IN NEURALGIA.

Attracted by the report of Dujardin-Beaumetz and Bardet on the properties of this agent, DR. FREDERICK PETERSON, of New York, has emphasized it in a number of neuralgic cases with satisfactory results. He administered it both in the form of pills containing 2 grains each, and a cordial with  $2\frac{1}{2}$  grains to the tablespoonful. He finds it a valuable analgesic, and has succeeded in curing with it a number of cases of cephalalgia, facial neuralgia, brachial neuritis, etc. In some cases of failure he believes that his doses were too small and that one should, in most cases, begin with doses of from 4 to 6 grains, repeated every two to four hours. Exalgine is very soluble in water containing a little alcohol, but only slightly soluble in cold water. It acts very energetically upon the cerebro-spinal axis in animals, giving rise to phenomena of impulsion, tremor and paralysis of the respiratory muscles. In non-toxic doses sensibility to pain disappears, but that of touch persists; it produces also a gradual but notable fall of temperature. Its effects are somewhat similar to those of antipyrin, but its effect upon sensibility is more marked and upon the thermogenic centres less. In therapeutical use exalgine produces no rash cyanosis or gastrointestinal irritation. It is eliminated by the urine modifying its secretion, and in diabetic polyuria it diminishes the daily amount of urine and the quantity of sugar.—*New York Medical Record*.

### INCOMPATIBILITY OF ANTIPYRIN WITH OTHER DRUGS.

M. CHARLES has called attention to the precipitate which is formed by mixing solutions of antipyrin and cinchona, and M. Ferand has made later some experiments which warrant him in saying that in mixtures containing antipyrin and cinchona all the active principles of the potion are precipitated and leave in the filtered liquid scarcely a perceptible trace of antipyrin and the alkaloids. He notices, as did M. Charles, that the precipitate is readily soluble in weak acids, from which he concludes that the potion does not become inert, as the precipitate should dissolve in the gastric juice.

M. Blainville, pharmacist, records a new incompatible with antipyrin; having had occasion to mix 4 grams of antipyrin and 5 grams of hydrate of chloral and 15 grams of water, he found the mixture became milky, then clearing, deposited an oleaginous liquid. Decanted, this liquid possessed neither the taste of antipyrin nor of chloral, but resembled coriander seeds.

Upon the subject of incompatibles, which are discovered each day by pharmacists, M. Ferand

remarks that they should avoid mixing substances as complex as antipyrin with chemicals capable of modifying its composition and, consequently, its physiological action.

Formulas the most simple, said he, such as distilled water sweetened, should be the rule when prescribing a new body used in therapeutics before all its chemical characteristics are thoroughly studied.—*La France Médicale*.—*Times and Register*.

### PICROTOXIN AS AN ANTIDOTE TO MORPHINE.

From experimental investigations A. BÓKAI (*Cent. für Klin. Med.*, No. 33, 1889) is convinced that picrotoxin is the most rational antidote to morphine. Picrotoxin and morphine produce antagonistic effects upon the respiratory centre, the latter paralyzing its action, while small doses of picrotoxin increase it and inhibit the paralyzing influence of morphine. Further, picrotoxin irritates the vaso-constricting center of the medulla and is, therefore, capable of hindering the rapid fall of blood pressure in morphine poisoning. The two agents likewise have opposing effects upon the hemispheres. Picrotoxin also deserves attention from the fact that it may be given in the place of the nux vomica preparations and may perhaps be found a good prophylactic for chloroform asphyxia.

### CHLOROFORM ADMINISTRATION.

The administration of chloroform in preference to ether is much more common in Europe than in this country. Several deaths having recently occurred in the Paris hospitals from the use of chloroform, the surgeons are beginning to seek a safer anæsthetic, and it is now proposed to substitute the chloride of methylene, or, more properly, *methylic chloroform*. PROF. REGNAULD has called the attention of the Académie de Médecine to this agent, which was formerly regarded with favor by Sir Spencer Wells and Richardson. Regnauld finds that in reality the so-called chloride of methylene is nothing but a mixture of four parts of chloroform and one part of methylic alcohol. Its action is very much slower than that of chloroform, but it is hoped that it will prove proportionately safer.—*N. Y. Medical Journal*.

### DEATH FROM SULPHONAL.

DR. R. R. PETITT reports a case of death from the administration of sulphonal. The patient, a woman 28 years old, was suffering from melancholia. She took 15 grains of sulphonal, and about an hour later the dose was repeated. Soon after she went to sleep and could not be aroused for twenty-four hours. Death occurred from failure of respiration forty hours after the dose was taken.—*Medical News*.

## SOCIETY PROCEEDINGS.

## Obstetrical Society of Philadelphia.

*Stated Meeting, September 5, 1889.*

DR. JOHN C. DA COSTA IN THE CHAIR.

DR. JOHN DA COSTA :

## AN EASY METHOD OF REPAIRING THE PERINEUM.

There is probably not any operation in gynecology which gives a woman so much relief as the proper restoration of a torn perineum.

In describing this operation I shall not say a word in regard to the anatomy of the perineum, which is the same as it was a hundred years ago. The same muscles are torn now as were torn then. This subject of tear of the perineum may seem to be a very simple matter; but when we consider that 20 per cent. of women have their perineum torn in first labors, and 4 per cent. in subsequent labors, it ceases to be a little matter, and becomes one of importance.

I do not claim anything new. The operation is the result of a combination of old ideas. It is an easy and simple method of repairing the perineum, and answers equally well whether the tear is long or short. I thought I had something new in the use of these rubber bars, when I got it up eight years ago, but afterwards found that one of my ideas had been anticipated twenty years before.

Mr. Lane, of London, in 1860, used ivory bars with small perforations, and reports thirty consecutive cases without a failure. Dr. Thompson, of Washington, used flat rubber bars with small holes in them, and reports fifty-three consecutive cases, all cured. Dr. Thomas, after speaking of the quill suture, leads us to infer that he used perforated bars, and states that he does not recall a failure in the operation.

I do not know how many present are believers in the idea advanced four or five years ago, at the meeting of the American Gynecological Society in this city, "that there is no such thing as a perineum;" but there certainly is a triangular body between the vagina on one side and the rectum on the other, and this triangular body is often torn through during labor, and becomes what I call a ruptured perineum. There are many ways of repairing it. Some are very simple, some are very striking but very useless; what I strive to do is to restore the perineum very much as nature made it. The operation is easy and the armamentarium is simple. We require a pair of scissors (I use a pair of blunt-pointed scissors), a perineal needle, a little silver wire and shot, a shot compressor, and two bars shaped like the cut.

Bar,  $\frac{1}{2}$  size.

The operation is begun at the bottom of the tear in the vagina. With one or two fingers in the rectum, I make a little slit at the lowest point and denude subcutaneously all the tissue that has been torn. I do not know how far up I go—it may be 2 inches, or even nearly the length of the finger. This depends altogether upon the extent of the tear. The important thing is to get rid of all the scar tissue. Unless this is done, good union will not be secured. After denuding up the proper distance the scissors are turned to the right and to the left, and each side denuded. Then, with four cuts of the scissors, the loosened cicatricial tissue is removed. A denudation of this kind freshens the torn perineum as I think no other method does. The first stitch near the bottom of raw surface is passed three-fourths of an inch from the edge of the cut portion, buried in the tissue the whole distance, and comes out at the same distance on the other side. The needle is then threaded with silver wire and withdrawn. The second stitch is put in the same way. The third stitch is started in the skin like the others, and three-fourths of an inch from the edge of the cut, carried along just under the edge of the denudation the whole way around. This is the most important stitch of all. It was the idea of the late Albert H. Smith, when one of the physicians-in-chief at the Nurses' Home some years ago. The stitches are buried throughout, and only three are used in the operation. All that is necessary is to bring them out in nearly a straight line.

Surface denuded, and stitches in place.

The wires are then slipped through slotted rubber bars, on each side, and shot-clamped on them. After the shot are clamped the ends of the wires are twisted over the median line and the ends passed through a piece of catheter. In twenty-

four hours there is swelling and a certain amount of inflammation. I then cut the wires off close above the shot, and this at once relieves the tension and the pain. Any desired dressing may then be applied, if it is thought advisable to use any dressing.

Operation finished, and bars in place.

What are the advantages of this operation? In the first place you have but three stitches. I think that probably every gentleman has seen perineæ operated on where there has been deep quilting, and have seen the tissue slough out because the circulation has been so interfered with that nutrition could not be maintained. These three sutures interfere very little with the circulation and they hold together the deep parts of the wound, which is very important. When inflammation takes place you cut the wires over the shot, the bars spread and relieve the tension, and prevent any tendency to sloughing, while still supporting the parts.

After the wound is closed, you may take a piece of catgut and whip up the edges in the vagina, and along the line of the raphé. This is not necessary unless we want to make a very perfect job. The operation is easily and quickly performed. I have never timed myself, and have never tried to do the operation in a hurry, but I accidentally found out how long it takes.

On one occasion, in thirty minutes from the time that I began, I had operated on two cases, and this included the time necessary to put one patient under ether from perfect consciousness to unconsciousness. The denudation is accomplished in four or five minutes.

This is a different operation from that in which the denudation is made in curved lines, and where another operation is required for any ex-

isting rectocle. The operation described above will include also a rectocele. It is better than another popular operation, which does not restore the triangle which nature made, but makes a beautiful skin-flap, which looks well from the outside, but affords no support.

I do not claim anything novel. It is simply a combination of ideas that I have picked up from time to time. In regard to the results of the operation, it is a rare occurrence to have a failure.

DR. J. PRICE: There are a few points about which I should like to speak in connection with this procedure and like procedures. As Dr. Da Costa has said, this is an old operation, and is illustrated in all the books. It is the old operation upon the posterior wall, and has the merit he referred to, of, in many cases, making a superficial or skin perinæum. The principle of suturing described is one not adopted in any other branch of surgery, and Dr. Da Costa would himself not apply this principle in any other portion of the body. He says that sometimes he denudes a distance of three inches. In no other part would he approximate such a surface with three sutures, and three sutures will not close it.

A word in regard to the denudation. He speaks of four clips of the scissors—the button-hole, the central, and the two lateral. In many cases it is impossible to make such a denudation. You will button-hole the flap many times. That was the trouble with the Smith and Jenks operation. It is difficult to make a clean denudation in the midst of scar tissue by such a method.

One of these illustrations shows what takes place in many perineal tears. The skin-perineum side is not harmed; but if you place your finger in the sulcus on one side, you will find a sense of resistance which is absent on the other side. The sulcus is a deep one, and is a lateral tear. As has been remarked by Dr. Deaver, "It is for all the world like the lateral cut for stone." In such a case the procedure is almost a unilateral one to bring up the pelvic floor. It is just such a state of affairs that Emmet had in view in his classical operation for the restoration of the pelvic floor or diaphragm, and he has most beautifully succeeded.

In regard to the use of this needle. Dr. Da Costa has referred to the fifty-three cases reported by Dr. Thompson of the Columbia Hospital; but he lost one or two from tetanus, and this bayonet was at the bottom of the tetanus. I look upon this needle as wholly unjustifiable in any surgery. No man has a right to have such a thing among his instruments. I am surprised that more do not die from such a stab, including, as it does, incongruous masses of tissue, skin, fat, muscles, vessels, and nerves. I remember, while a student, of seeing a death from such a stab. I use the smallest sewing needle possible.

These procedures are very old, and are illus-

trated in all the old works. I consider all two-or-three-stitch methods of closing the perineum as emphatically imperfect procedures.

DR. JOHN C. DA COSTA: What Dr. Price has said in regard to one of these illustrations has nothing to do with the subject under discussion. He refers to a tear of the vagina, which has nothing to do with a tear of the perineum. If there is a line of cicatricial tissue on one side, we do not need to denude both sides to repair the condition. It is a simple matter to remove the scar tissue and sew it up, as in any other surgical operation.

I am sorry to hear this tirade against this needle. Some very able men use this needle, and they get very good results. Albert H. Smith, who did a good deal of gynecological work, used a needle much like this. One of the most successful abdominal surgeons in Philadelphia uses a needle much like this. Surgeons in all branches of surgery use needles very like this—either a little more or a little less curved. One who came from Europe a year ago showed me a long, curved needle which he brought with him and said was Tait's needle. It was precisely similar to one which I have had in my box for some years for use in complete laceration of the perineum. This is only the Baker-Brown needle modified.

I do not know that Dr. Price has said anything against this operation. He has talked a good deal about the needle and about a tear that does not apply at all. I can only say, that, despite his fears, the operations are almost uniformly successful. Any one who can do the ordinary quill operation can do this. After analyzing the various operations eight years ago, I found that the best results were obtained by the old-fashioned operation. The quill operation, however, made a V-shaped sinus to the bottom of the wound, and sometimes caused a great deal of trouble; and it was to overcome this objection that I substituted the hard rubber bars with the wires running through.

(To be continued.)

## DOMESTIC CORRESPONDENCE.

### LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

*Meeting of the Section on Practice, New York Academy of Medicine—Dr. A. Jacobi on Chronic Peritonitis—Discussion by Drs. Francis Delafield, Wm. H. Thomson and L. Weber.*

At the October meeting of the Section on Practice of the Academy of Medicine Dr. A. Jacobi read a paper on "Chronic Peritonitis, with Special Reference to the Differential Diagnosis of Some

of its Varieties." Most of the cases, he said, were of a secondary nature, with a great variety of causes. Having mentioned a considerable number of these, he referred to the case of a young woman whom he saw dying of acute peritonitis, who had been affected with purpura for some weeks. At the autopsy the peritonitis was found to have resulted from the rupture of some of the vessels of the diaphragm. He considered the most frequent cause of peritonitis a preceding peritonitis, and stated that in most cases examined after death the positive proofs of one or more attacks previous to the fatal one were found. He did not remember ever having seen a case of perityphlitis which did not exhibit the adhesions, discolorations and contractions due to former peritonitis, and he thought it probable that there were but few, if any, cases of foreign bodies entering the vermiform process unless the latter had previously lost its elasticity and contractility by an inflammatory change.

Alterations of the mucous membrane of the intestine, he went on to say, constituted the initial stages of local peritonitis in many instances, and of general peritonitis in some. It was not only the *intima* and the submucous tissue which suffered, but the muscular layer was also implicated in the morbid process. No morbid process could remain isolated in a locality supplied with an active blood and lymph circulation, and hence a simple intestinal catarrh might grow to be an enteritis, the enteritis a peritonitis. This condition of things was still more frequently observed in cases of intestinal ulceration, both acute and chronic. Even without perforation, an ulceration would lead to peritonitis which was mostly local, but liable to change into an acute attack under favorable circumstances. Where there was an open ulcer, or even one that had cicatrized months or years before, in the stomach or in the intestines (no matter what its nature might be), we frequently found opposite it a local peritonitis. In the peritoneal covering there was a thickening, circumscribed and distinct, which in recent cases was rather soft and accompanied by much vascular injection. In old cases the original cell proliferation had undergone organization and hardening, and the thickened spot was gray, or whitish and hard. It had lost its elasticity, and was very apt to burst under a moderate amount of pressure; thus leading to perforation. In the midst of apparent health intestinal perforation would often set in, and death ensue within a day; and at the autopsy the physician would learn that the patient was the victim of the perforation of the cicatrix of a typhoid ulceration perhaps contracted a dozen years before.

The diagnosis of chronic peritonitis, he said, was frequently missed. Unsuspected adhesions often existed around tumors, movable kidneys became fixed, intestines glued together, all with-

out recognizable symptoms. In chronic peritonitis respiration was not necessarily accelerated; and especially was this symptom lacking in pelvic peritonitis, perimetritis and pericystitis. There might be occasional vomiting, particularly when there happened to be an intercurrent acute catarrh; but there were other conditions, as, for instance, renal and biliary colic, which were more likely to exhibit this symptom, and to an excessive degree. It was often entirely absent, and even in many acute cases of peritonitis this was the case. Constipation was frequent, but diarrhœa, on the other hand, was not unusual. The horizontal position was often uncomfortable, but a common colic, depending on gas not absorbed or expelled, also caused drawing up of the knees. When the horizontal posture was shunned in chronic peritonitis, however, the patient was more apt to remain quiet with raised knees than one who was suffering from flatulency; in which condition the limbs were generally tossed about continually.

While the abdomen was apt to be tumid, it was to be remembered that general adiposity is most fully developed in this region, that women who have borne children are apt to have a large and prominent abdomen, that the abdomen of a healthy infant is so large as to measure one-third of its length, that a simple hysterical dilatation and inflation may simulate the tumefaction resulting from peritonitis, and that there may occur a local dilatation of the intestine from habitual constipation only. Moreover, in hysteria there was sometimes met with an œdematous swelling of both hypogastric regions; which would still more seriously complicate the diagnosis. The surface of the abdomen exhibited networks of dilated veins more frequently in peritonitis than in any other condition except certain hepatic diseases. Inspection might also reveal solitary convolutions rising above the surface, and palpation and percussion might lead to the discovery of exudations of various sizes and shapes; these consisting of either organized material, thickened omentum, or intestines glued together. Fluctuation would show the presence of fluid more readily than percussion, which might fail in this, that there might be adhesions between the parietal peritoneum and intestines in the flanks. The gas contained in the adherent bowel might yield a tympanitic percussion note although the region might be filled with fluid. A change of position, from one side to the other, or from the horizontal to the vertical posture, or *vice versa*, might contribute to dispel the doubt.

A chronic peritonitis was sometimes diagnosed in the following manner: The patient lies on his back, with the extremities now extended and now flexed. Pressure is tried: hard or light, sudden or gradual, superficial or deep. According to the seat of the pain experienced, inflammation or adhesion is most manifest. When deep

pressure is first made with the palm or finger there may perhaps be no pain. Relieve the pressure suddenly, and a local, very distinct, and circumscribed pain may be felt. Repetition of the experiment will always give the same result; the symptom being elicited by the sudden change in the relative position of the bowels. Not only pain, but the presence of hard, floating exudations can be distinguished by this and similar manœuvres.

Pain of varying degree and persistency, he continued, was a very frequent symptom in chronic peritonitis. Its intensity often depended on the degree of irritation or congestion present, and acute attacks were frequent where there was a cause for exacerbations. Extensive peritonitis in the pelvis might not give rise to pain, except such as resulted from defecation, sexual intercourse, or micturition. In some cases the pain of chronic peritonitis could not be distinguished from the enteralgia produced by other causes, such as abnormal contents, fermentation, and flatulency. Indeed, the anatomical causes of chronic peritonitis gave rise to these very conditions; for by it the intestinal movements were retarded, and from it there might result stenosis and adhesions, interfering with every function.

The results of chronic peritonitis were very various. A simple attack of acute exudation might shape the future of the patient, and the histories of previous acute attacks were often not remembered. Experience showed that the most extensive changes might occur without any known history whatever.

The concluding portion of the paper was devoted to an exhaustive consideration of the important form of chronic peritonitis known as *tabes mesenterica*. The different manifestations in different cases of this affection Dr. Jacobi thought went to prove that there were several distinct varieties of *tabes*, depending on different causes and attended with varying anatomical alterations. Besides the simple secondary hyperplasia of the mesenteric glands, resulting in obstruction, and the tubercular infiltration terminating in the severe disturbance of function, he said there was a third condition which led to symptoms constituting what is known as *tabes mesenterica*, viz.: chronic tubercular peritonitis. The diagnosis of tubercular peritonitis was apt to be quite difficult, and there were many chronic cases which could not be differentiated from non-infectious peritonitis and simple inflammatory processes. There were, however, cases of tumid abdomen with atrophy, of both an acute and chronic character, in which the nature of the affection could be made out with some degree of certainty. The prognosis of so called *tabes mesenterica* was always uncertain except in the very worst cases. It was absolutely fatal when there was peritoneal and glandular tuberculosis complicated with or de-

pending on generalized tuberculosis. In cases where the diagnosis of a non-infectious hyperplasia of the mesenteric glands could be made out, it was decidedly more favorable. When the diagnosis of chronic peritoneal tuberculosis had been made, the case was less promising; still the possibility of recovery, or partial recovery, was not excluded.

In the discussion on the paper Dr. Francis Delafield said that there were few morbid conditions of greater clinical interest than chronic peritonitis, as it was constantly coming up for diagnosis, and as many mistakes regarding it were made as about any affection with which he was acquainted. He had been accustomed to look at the disease with reference to the anatomical conditions present, and hence divided the cases into three classes: *first*, those in which there were simply adhesions of connective tissue; *second*, those in which there were present both adhesions and fluid, either serous or purulent; and *third*, those in which there was diffuse thickening with fluid, but without adhesions.

In the first class of cases the condition was often not recognized until it was revealed by an autopsy. The symptoms often corresponded very nearly with those met with in what is known as "irritable colon," and it was very difficult to distinguish between the two. In many cases it was also difficult to distinguish it from tubercular peritonitis, when, in addition to connective tissue adhesions, there was present a large waxy liver. Still another condition with which it was likely to be confounded was a dilated pylorus, in which the stomach felt to the touch almost precisely like a mass of intestines matted together. Pain in different parts of the abdominal cavity gave the physician as much trouble in the way of making a diagnosis, and there was, in fact, very little to distinguish the pains due to different causes from each other.

In the second class of cases it was often difficult to distinguish the condition from tubercular peritonitis, and the diagnosis between it and carcinoma was also difficult. Again, we were likely to be puzzled by the shape which the peritonitis took. In certain instances fluid was met with in different parts separated by partitions, and there were the physical signs of a tumor with fluid. What seemed like a tumor, however, was simply the intestines matted together.

In the third class of cases it was difficult to distinguish the affection from tuberculous peritonitis, from multiple cancer, and from cirrhosis of the liver. Especially was it hard to distinguish it from the latter when the capsule of the liver was involved, since we were apt to have the gastric symptoms and the vomiting of blood which are so often met with in that affection.

Dr. Wm. H. Thomson called attention to a feature which appeared to be diagnostic of cancerous peritonitis, viz.: a remarkably low per-

centage of urea in the urine (a condition not found in tuberculous or other forms of peritonitis), and related two cases in which he had found it present. He had also found in such cases a diagnostic sign which Germain Sée had called attention to in cancer of the stomach, viz.: tenderness and enlargement of the post-clavicular glands. Again, in cancerous peritonitis there were not the same fluctuations in temperature that were met with in the tubercular form. As to tubercular peritonitis, he had met with one case in a young man in which there was distinct redness about the umbilicus, a sign of this affection which Wilks had pointed out. When ascites was present in chronic peritonitis it rendered it very difficult to distinguish between this condition and cirrhosis of the liver, and especially where the history pointed to perihepatitis. The previous history of the patient, as to habits, etc., however, would generally throw some light on the question whether in any given case we had to do with cirrhosis or not.

Dr. L. Weber said that he had never seen a case of chronic peritonitis, properly so called, which was not infectious in its nature. Such cases as those described in the early part of the paper he would look upon as ones in which there had previously been acute peritonitis, with its accustomed results. Of these, adhesions were the most frequent, and they often had the effect of impeding the functions. He had no objection to calling such cases chronic peritonitis, although personally he did not consider them as true instances of general chronic peritonitis. They simply exhibited the results of adhesions caused by the acute disease, and when in such cases a fatal result occurred the patient really died of acute peritonitis due to perforation. As to *tabes mesenterica*, he believed that this was always a tuberculous affection, and he incidentally remarked that he had been much impressed by the reports of the favorable results which had recently been obtained in this disease by opening the abdomen and dusting the affected parts with iodoform.

## MISCELLANY.

---

OHIO STATE SANITARY ASSOCIATION.—We have received from Dr. R. Harvey Reed, the energetic Secretary of this Association, a programme of the seventh annual meeting, to be held in Dayton, O., on the 21st and 22d inst. The following papers will be read:

"The Relations of Theologians to Sanitarians," Dr. D. J. Snyder, Scio; "Sanitation vs. Medication," Dr. S. P. Bishop, Delta; "Recent Advances in Etiological Science," Dr. E. R. Eggleston, Mt. Vernon; "Sanitation in Small Villages," Dr. Austin Hutt, Waverly; "Bodily Comfort as a Sanitary Object," Dr. G. C. Ashmun, Cleveland; "Influence of Climate Upon So-called Malarial Fevers," Dr. Wm. Owens, Cincinnati; "The Cadaveric and Vital Alkaloids," Prof. C. C. Howard, Columbus; "Will

General Sanitation Ever Become Popular?" Dr. John McCurdy, Youngstown; "Address of Welcome," Hon. A. D. Witt; "Response to the Address of Welcome;" Dr. R. Harvey Reed, Mansfield; Poem, "Bacteria, or the Flies we Feed on and the Bugs that Kill Us," Dr. W. S. Battles, Shreve; President's address—1. "The use of Pork; its relations to Scrofula and Consumption." 2. "Mosaic prohibition of Pork, as taught by the Scriptures, and the prejudices of most of the Ancient Nations to its use as food." 3. "Description of Trichina-Spiralis and their dangerous effect on the human body," Dr. D. H. Beckwith, Cleveland; "Food as a Therapeutic Agent," Dr. H. J. Herrick, Cleveland; "The Best Food for Man," Dr. J. D. Buck, Cincinnati; "The Relation of Water Supply to Disease," Dr. H. J. Sharp, London; "The Necessity of Uniform Rules, Regulations, Reports and Records of Local Boards of Health," Dr. F. Gunsaulis, Columbus; "The Sanitary Teachings of the Bible," Prof. E. T. Nelson, Delaware; "The Hygiene of the Chronic Insane," Dr. J. W. Scott, Cleveland; "Garbage and Night Soil Crematories From a Financial and Practical Standpoint," Dr. Geo. I. Garrison, Wheeling, W. Va.

Arrangements have been made for reduced railroad rates on the certificate plan, full particulars of which may be learned on application to the Secretary at Mansfield, Ohio.

*Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 10, 1889, to October 25, 1889.*

So much of par. 2, S. O. 241, October 16, 1889, from this office, as directs Capt. Louis Brechemin, Asst. Surgeon, to report for duty at Ft. Apache, Ariz. Ter., is revoked. He will report in person to the commanding officer, Presidio of San Francisco, Cal., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889. Capt. Peter R. Egan, Asst. Surgeon U. S. Army, on being

relieved from duty at Camp Eagle Pass, Texas, will report in person to the commanding officer, Ft. McIntosh, Tex., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

Capt. William J. Wakeman, Asst. Surgeon U. S. A., relieved from duty at Ft. Walla Walla, W. T., and will report in person to the commanding officer, Ft. Bidwell, Cal., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

Capt. William B. Davis, Asst. Surgeon U. S. A., relieved from further duty at Ft. Porter, N. Y., and will report in person, upon expiration of his present sick leave of absence, to the commanding officer, Ft. Preble, Maine, for duty. S. O. 248, A. G. O., October 24, 1889.

First Lieut. Paul Clendenin, Asst. Surgeon U. S. A., relieved from duty at Ft. McIntosh, Tex., and will report in person to the commanding officer, Camp Eagle Pass, Tex., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

Capt. Alonzo R. Chapin, Asst. Surgeon U. S. A., relieved from duty at Newport Bks., Ky., and will report in person to the commanding officer, Ft. Yates, Dak., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

First Lieut. Henry I. Raymond, Asst. Surgeon U. S. A., upon being relieved from duty at Ft. Bidwell, Cal., will report in person to the commanding officer, Newport Bks., Ky., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

Capt. William C. Shannon, Asst. Surgeon U. S. A., relieved from duty at Ft. Yates, Dak., and will report in person to the commanding officer, Ft. Apache, Ariz. Ter., for duty at that station. Par. 7, S. O. 248, A. G. O., October 24, 1889.

Asst. Surgeon Marcus E. Taylor, U. S. A., relieved from duty at Ft. Stanton, N. M., and ordered to Boise Bks., Idaho. Par. 10, S. O. 242, A. G. O., October 17, 1889. Surgeon Joseph R. Gibson, U. S. A., relieved from duty at Ft. Sheridan, Ill., and ordered to Governor's Island, New York Harbor. Par. 10, S. O. 242, A. G. O., October 17, 1889.

Asst. Surgeon Louis M. Maus, U. S. A., relieved from duty at Ft. Porter, N. Y., and ordered to Ft. Stanton, N. M. Par. 10, S. O. 242, A. G. O., October 17, 1889.

Asst. Surgeon Edwin F. Gardner, U. S. A., relieved from duty at Ft. Lewis, Col., and ordered to Ft. Porter, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

Surgeon Clarence Ewen, U. S. A., relieved from duty at Madison Bks., N. Y., and ordered to Willet's Point, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

Surgeon Alfred C. Girard, U. S. A., relieved from duty at Boise Bks., Idaho, and ordered to Ft. Niagara, N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

Asst. Surgeon John D. Hall, U. S. A., relieved from duty at Ft. Niagara, N. Y., and ordered to Madison Bks., N. Y. Par. 10, S. O. 242, A. G. O., October 17, 1889.

First Lieut. William P. Kendall, Asst. Surgeon U. S. A., leave of absence extended one month. Par. 6, S. O. 244, A. G. O., October 19, 1889.

Capt. Edgar A. Mearns, Asst. Surgeon U. S. A., granted leave of absence for two months. Par. 5, S. O. 244, A. G. O., October 19, 1889.

*Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending October 10, 1889.*

Surgeon John Vansant, granted leave of absence for fifteen days. October 16, 1889.

Surgeon C. B. Goldsborough, leave of absence extended thirty days on surgeon's certificate of disability. October 18, 1889.

Asst. Surgeon T. B. Perry, ordered to temporary duty at San Francisco, Cal. October 15, 1889.

Asst. Surgeon G. T. Vaughan, when relieved, to proceed to Evansville, Ind., for temporary duty. October 9, 1889.

### THE APPLICATION OF FORCEPS TO TRANSVERSE AND OBLIQUE POSI- TIONS OF THE HEAD. DESCRIp- TION OF A NEW FORCEPS.

*Read in the Section of Obstetrics and Diseases of Women at the Forty-  
fifth Annual Meeting of the American Medical Association  
June, 1889.*

BY HENRY D. FRY, M.D.,  
OF WASHINGTON, D. C.

The obstetric forceps is constantly undergoing modifications of construction, and there is no part of the original instrument that has not been, in some manner, altered to suit the ideas of the designer. Blade, shank, lock and handle have been changed in shape and size. Nevertheless, it may be said, but two distinct alterations of the original Chamberlen forceps have been made. They are the pelvic curve of the blade, and the application of axis traction.

Varied as are the designs, the method of employing the forceps is as little fixed as the instrument itself. The application of the blades to the sides of the pelvis, disregarding entirely the position of the head; the application of the blades to the sides of the head whenever practicable; intermittent manual traction; continuous mechanical traction; the advisability or non-advisability of compressing the fetal head; the utility or inutility of lever action, express some of the diverse opinions held on the subject. This lack of uniformity proves the non-existence of a scientific basis. Labor is absolutely a physical act, accomplished according to a well defined mechanism, therefore the laws governing the application of artificial aid should be precise and absolute. With the earnest desire that progress may be made in this direction, I present my communication to the consideration of the members of the Obstetrical and Gynecological Section of the American Medical Association.

The following propositions are advanced, and suggest for discussion both the methods of employing the forceps, and the modification of its construction.

1. *The forceps should always be applied to the sides of the child's head.*

2. *The obstetrician should not wed any single form or design of instrument, but he should be equally expert with several, and employ one or another according to the circumstances of the case, always selecting that instrument which best enables him to apply the blades to the sides of the head.*

First Proposition. *The forceps should always be applied to the sides of the child's head.* This is styled the French method, because it has been so generally advocated by the obstetric authors of France since the time of Baudelocque. Poullet,<sup>1</sup> of Lyons, in a recent article on this subject states that the doctrine, French in its conception, has unfortunately remained exclusively French, in the sense that it has never been, even partially, adopted by the obstetricians of other nations. In spite of the theoretical efforts of the French masters, the practice has diminished gradually in importance and in frequency of application. In England, Austria and Germany the forceps are always applied symmetrically—one blade to the right, and the other to the left of the pelvis. Poullet further states that even in France the custom is so changed that now the majority of physicians and many specialists operate in like manner. When the head is at the superior strait, he says no one counsels the oblique application of the instrument—an impossibility with the curve of Levret. Under these circumstances, all agree that the head must be seized in whatever manner possible. When, however, it is in the excavation, the classic French authors at least in theory advise oblique application.

In reply to a letter asking for information as to the method generally pursued by the Paris accoucheurs, Dr. Paul Bar kindly writes me:—"When we have to apply the forceps to transverse positions of the vertex, head in excavation or above superior strait, we seek, not to grasp the head from forehead to occiput, but we direct our efforts to apply one blade anteriorly and the other posteriorly."

While it may be that in certain countries the forceps are usually applied to the sides of the mother's pelvis, Poullet undoubtedly errs when he states that the opposite method "has never been, even partially, adopted by the obstetri-

<sup>1</sup> "Nouvelles Archives d'obstétrique et de Gynécologie." Paris, 1887, pp. 44-62.

cians" of those countries. Smellie, one of the earliest English workers in this field, paid strict attention to the situation of the child's ears in relation to the mother's pelvis, and invariably sought to apply the forceps to the sides of the head. Numerous operators, in England and on the Continent, follow the same practice.

In order to ascertain the opinion of the profession in this country, circular letters were addressed to all the teachers of obstetrics, and to numerous practitioners located in every State of the Union. Eighty-two replies were received and the views expressed may be summarized as follows: Forty-two always apply the blades to the sides of the head when possible. Thirty-one always apply the blades to the sides of the mother's pelvis and disregard the position of the head. Nine recognize no rule and apply according to either method.

Various exceptions to these methods were presented.

A number who advocate the first method apply the forceps at the sides of the pelvis when the head is high (transverse or oblique), and after bringing down the presenting part, remove and reapply the instrument to the biparietal diameter of the head. Others, entertaining the same view, attempt to rectify the position of the head, when transverse, before applying the forceps. This is done by external manipulation, by the hand in the vagina, alone, or combined with external manipulation, and with the vectis or forceps.

On the other hand, some of those who follow the principle to adapt the forceps to the sides of the pelvis apply them, under some circumstances, in high situations, to the sides of the head. Several obstetricians employ, in these cases, special forceps with long straight blades.

The advantages of applying the blades to the sides of the head are well known and generally admitted. Reasons exist, however, to prevent the universal adoption of the custom. Its strongest advocates admit it is often impossible to grasp the head in such manner with the instruments now in use. The difficulty arises with high situation of the part when occupying an oblique position, and with transverse positions whether at the brim or in the cavity.

On the other hand some, and among the number many distinguished obstetricians, believe it unnecessary. They claim the application of the instrument to the sides of the pelvis permits the head to rotate within the blades and the normal mechanism of labor is not embarrassed. These operators, we must bear in mind, exercise intelligent supervision, removing and reapplying the instrument when necessary and encouraging the progress of the head according to the natural laws of labor.

By many practitioners the forceps is used without any attempt being made to ascertain the posi-

tion of the head. It is easy to apply the blades to the sides of the mother's pelvis and the head can usually be delivered in that manner. No attention is paid to the laws governing the passage of the passenger, and brute force supplies the scientific employment of artificial aid.

Transverse positions of the head offer special difficulties in the way of applying the blades to its sides. The most aimed at is to locate the instrument in one or other oblique diameter of the pelvis, seizing the head with a blade in front of one ear, and the opposite behind the other ear. The higher the head is situated the greater the difficulty, and when engaged at the brim few attempt to pass the blades in any manner except to the sides of the mother's pelvis. Such a grasp, besides being less secure, exerts injurious compression upon the fetal head. If the forceps be patterned after the Simpson model forward rotation of the occiput may take place within the blades, but if the instrument possess greater compressive power, rotation is hindered and the head is dragged into the pelvis transversely. If, under these circumstances, the forceps be not removed and rotation effected by nature, or artificially with the hand, or with the instrument reapplied to the sides of the head, one of the following results may be anticipated:

1. Continued and forcible extractive efforts may succeed in delivering the head, but it will be born with its occipito-frontal diameter in the transverse of the pelvic outlet, causing, as a rule, laceration of the mother's soft parts, and injurious, if not fatal, compression of the fetal head.

2. Forcible efforts to deliver the head fail, and it becomes obligatory to attempt to push up the presenting part, and if the position cannot be rectified, to deliver by turning, or,

3. Failing to elevate the head, craniotomy is the only alternative.

An important consideration demanding notice, is the comparative frequency of transverse positions of the head. Many obstetric writers claim they are rare; and some of the gentlemen who replied to my circular letters expressed this opinion. My limited experience is opposed to such a view, but I should hesitate to give voice to the contrary were my position not fortified by good authority. During the past six months I have had occasion twice to apply the forceps to the head while transverse in the excavation. Lusk<sup>2</sup> states that when the head is said to occupy the oblique diameter it is not intended in a mathematical sense. It simply implies it is deflected from the transverse. How easily can one fail to recognize this deflection? Let us remember that the anatomical difference between an oblique and transverse position is limited to a space upon the side of the mother's pelvis scarcely more than one

<sup>2</sup>"Science and Art of Midwifery," New York: D. Appleton & Co., 1881, foot note p. 163.

inch in extent. One who considers the position rare, is misled by his conviction. Finding the small fontanelle to the mother's right or left side, and the sagittal suture passing across the pelvis, he looks upon it as one of the oblique positions. A more painstaking examination might reveal to him the above suture passing directly parallel to the transverse diameter of the pelvis, and the fontanelle situated at its extremity. A digital examination made while the woman occupies the left lateral posture contributes to an erroneous conclusion. Advantageous as this obstetric position may be for other purposes, it does not compare with the dorsal when our object is to ascertain the relative anatomical positions of the presenting parts of the fœtus and the mother's pelvis. Abdominal palpation gives little aid in arriving at a differential diagnosis between transverse and oblique positions of the head.

In cases of pelvic deformity with contraction of the conjugate of the brim, it is a well established rule that the head occupies the transverse position. Doubtless, minor degrees of pelvic contraction, and disproportionately large fetal heads, exist as causal agents of these positions more often than suspected. The opposite conditions, a roomy pelvis or small head, also tend to produce, and to maintain in the excavation, transverse positions by failure to secure flexion.

In many unrecognized cases of transverse position, rotation relieves the difficulty and labor ends normally. In others, nature fails to correct the position and artificial aid is demanded, consequently the comparative frequency of transverse to oblique positions is greater in forceps cases than in those which terminate without such assistance. Failure to rotate will delay labor indefinitely. Binault<sup>3</sup> extracted with forceps a fœtus which was in an advanced state of putrefaction. The mother had been in labor fourteen days, and the head of the child occupied the left occipito-iliac transverse. Four children had previously been born to her with easy labors, so that failure to rotate from a transverse position was the sole cause of delay in this case.

Charpentier and Cazeau describe these positions fully, and give explicit directions for the application of the forceps. Cazeau,<sup>4</sup> speaking of the comparative frequency of different occipital positions, says that in the results given, "no question seems to be made of the varieties we have designated as the transverse ones, and it is highly probable that they have been approximately added to one of the four preceding groups, for these positions are not very unusual; indeed, I have often met with them myself at the clinique." Transverse positions, he adds, are more common than R. O. A., and left occipito iliac transverse is

more frequent than right. Mme. Lachapelle claims that transverse positions are more often met with than R. O. P. Charpentier<sup>5</sup> writes: "One of the most frequent calls for interference is absence of rotation, the head being often transverse, but usually oblique, since these positions, as we have seen, are the fundamental, the others being simply varieties or consequences." Baudelocque, Moreau and Ramsbotham classify these positions. Although Playfair<sup>6</sup> follows the majority of British obstetric authors, by describing only the four oblique positions of the head, he says: "Until fairly passed the brim, it more frequently lies in the transverse than has generally been supposed." Poulliet,<sup>7</sup> in his article referred to, mentions the frequent occasions that arise at the Lyons clinique for using forceps in transverse positions. He recognized the absence of flexion in these cases and designed his angular forceps with parallel blades to rectify it. Spiegelberg<sup>8</sup> makes no distinction between transverse and oblique positions. The first vertex position is described as follows: "The back of the child looks to the mother's left, and the sagittal suture runs in the transverse or oblique diameter." His second vertex position is the reverse. He further says: "Occasionally the head passes transversely through the pelvic canal, and the sagittal suture is at the outlet in the transverse diameter."

"Deep transverse position of the head. The delayed rotation around the long fetal axis is due to an absence of resistance to the progress of the fœtus. If the cause lies in the smallness of the head, or in the width of the whole pelvis being occasionally above the normal, the head may also emerge in the same diameter." Again he adds: "Since the accomplishment of rotation sometimes occupies a considerable length of time, the deep transverse position may cause a delay which is not without danger and may require artificial interference. Moreover the skull in the deep position is effected by a marked biparietal obliquity, the anterior parietal bone presents, its eminence appears beneath the pelvic arch, the great and small fontanelles lie far back, and are directed straight to the sides."

Without pursuing this line of investigation further I hope sufficient authority has been presented to support the statement advanced, that transverse positions of the head at the brim and in the excavation are not infrequent. When they persist, artificial aid is called for; moreover the application of forceps to the biparietal diameter when so situated is particularly difficult and more often impossible.

The difficulty is due to lack of a proper instru-

ment. Forceps with the usual pelvic curve is valueless. Only when this instrument is applied one blade to each side of the mother's pelvis, and the concave edge directed forwards, is it placed so that the pelvic curve conforms to the axis of the pelvic canal. With the forceps inserted in such manner, however, it is impossible to grasp the head in the biparietal diameter when situated either transversely or obliquely. In proportion as the instrument is turned to one side or the other for the purpose of grasping the sides of the head, the pelvic curve of the blades departs from the line of the pelvic axis and the tip of the anterior blade is projected backwards. Not only is the pelvic curve of the classic forceps of no value in these cases, but it complicates its introduction. It becomes necessary at one time to apply the male blade anteriorly, and at another the female. On this account some obstetricians employ, for high transverse positions of the head, long forceps with straight blades.

Antero-posterior Forceps  
Front view

Antero-posterior Forceps  
Side view

To overcome these disadvantages I have designed a forceps curved on the flat. The introduction is simplified because the same blade is always the anterior and the opposite the posterior. The pelvic curve being upon the flat surface, the head can be seized in its biparietal diameter, whether high or low, or whether placed obliquely

or transversely. The curve adopted is the result of experimentation upon fresh foetal heads and articulated female pelvises, and corresponds closely to the pelvic curve on the edge of the classic forceps. The instrument is furnished with a compressive screw for use with the axis-traction attachment, which consists of a steel rod having a handle at one extremity and a hook at the other. The hook fits closely into the fenestrum on the anterior blade and cannot injure the soft parts of the mother. The compressive power of the forceps is about equal to the Hodge, Wallace, and such instruments that are intended for application to the sides of the head.

By seizing the head in its biparietal diameter with the long axis of the blades, parallel to the occipito-mental diameter, we are better able to control flexion and rotation of the head and to deliver by imitating the normal movements of labor. There is also less danger of injuring the child. Lusk<sup>10</sup> states that forceps at the brim is dangerous to the child, "from the rarity of the occasions which permit the blades to be applied to the sides of the head, to which the cephalic curve is alone adapted." This danger is again referred to by Lusk when discussing the paper on "Injury of the Fœtus During Labor,"<sup>11</sup> read by Dr. Parvin before the Philadelphia County Medical Society. He points out the danger of destroying the respiratory sense by injury to the medulla when the head is compressed for some time with the blades applied from occiput to forehead. At the same meeting Dr. Goodell directed attention to the risk of destroying the child by pressing the cord between the blade of the forceps and the occipital bone. This accident he was sure had occurred at his hands, and he attributed it, as well as cases of facial paralysis he had repeatedly seen, to the blades of the forceps not being applied exactly to the sides of the head. Dr. Parrish has also reported<sup>12</sup> several cases of still birth evidently due to compression of the cord when coiled around the neck. "Only," he says, "when the instrument is applied to the sides of the head, with the long axis of the blades parallel to the occipito-mental diameter, is the cord safe."

Objection may be made, on theoretical grounds, to the application of forceps with antero-posterior blades to the head when engaged transversely in the contracted brim, for the reason that the instrument encroaches upon the narrow diameter.

<sup>10</sup> Science and Art of Midwifery. Appleton & Co. New York, 1884, pp. 315.

<sup>11</sup> New York Medical Journal, Vol. xvi, Nos. 22 and 23, pp. 606-614. In this article Dr. Parvin stated that contused wounds usually followed difficult delivery with forceps, and resulted if the blades were applied obliquely or antero-posteriorly to the head. In reply to my circular letters, one operator stated that he had destroyed the sight of an eye by oblique application of the blades to the head when high.

<sup>12</sup> Journal of the American Medical Association, Vol. xii, No. 18, p. 613.

<sup>13</sup> Antero-Posterior Compression Forceps for Application at the Brim of Flat Pelvis. British Medical Journal, Feb. 2, 1886, p. 172.

On the contrary, this is an advantage, as the ability to compress the biparietal or bitemporal diameter of the head more than compensates for the space occupied by the blades. This view has happily been confirmed by Dr. Sloan, of Glasgow, in a recent communication<sup>12</sup> to the British Medical Association. The antero-posterior forceps with which he experimented is a powerful compressor, the greatest distance between the blades when closed being  $1\frac{1}{2}$  inches. The instrument was designed for application at the brim of flat pelvis, and "is never to be used until craniotomy is the only resource left." Trials were made with fresh foetal heads and dried pelvis, and the action of the forceps compared favorably with that of Simpson's.

Dr. Sloan had five opportunities to test the instrument in cases of obstructed labor, and the results were as follows:

Cases 1 and 2 were unsuccessful and had to be terminated by craniotomy.

*Case 3.*—Flat pelvis. Simpson's forceps failed; Sloan's antero-posterior forceps applied. Head brought down in fifteen minutes and delivered with straight forceps. Child made feeble efforts to breathe and died.

*Case 4.*—Flat pelvis, with true conjugate about  $3\frac{1}{2}$  inches; Simpson's forceps failed; Sloan's applied and child readily delivered alive.

*Case 5.*—Flat pelvis, true conjugate  $2\frac{3}{4}$  inches; child dead. Simpson's forceps failed; Sloan's completed labor promptly.

The instrument designed by Dr. Sloan is intended only to compress and bring the head through the contracted brim. To complete labor it is necessary to remove the anterior blade and apply another instrument, or deliver with the posterior blade, combined with supra-pubic pressure.

The use of the instrument which I offer is not restricted to labor in flat pelvis, but to all cases in which, from failure to rotate, the head is situated transversely or obliquely. If necessary, it can be used to compress as well as to make traction or rotate, and delivery can be completed without changing to a different forceps. I have had but one occasion to test the instrument in obstructed labor, and it left nothing to be desired. The woman, a primipara, æt. 15 years, had been in labor thirty-three hours when I saw her. The waters had been evacuated twenty-eight hours, the os dilated and retracted, the head was engaged at the pelvic inlet in the transverse diameter, with occiput to right, the promontory of the sacrum projecting well forwards. The blades were easily applied to the biparietal diameter and the head brought down, rotated and delivered. Moulding and elongation of the head had so diminished the biparietal diameter that very slight compression brought the handles in contact. The woman recovered and was able to be

up on the tenth day: The child, which was at term and weighed  $6\frac{1}{2}$  pounds, was born dead. The conjugate diameter measured  $2\frac{3}{4}$  inches. This case offered a severe test of the value of the forceps in labor obstructed by diminished conjugate, as the deformity was to the limit at which it is possible to deliver a fully developed child without mutilation. Turning was out of the question, Cæsarean section not justified, and craniotomy the only resort, if forceps failed. The use of the traction rod is designed for application when the head is high. As soon as the part is brought through the inlet the rod can be removed and traction made with the handles. Besides simplicity, it offers these advantages over other axis-traction attachments:

Traction made with the rod approximates the blades and increases the security of the grasp of the instrument.

The amount of compression exerted is, to some extent, in proportion to the force required to deliver the head.

e, d, Axis of inlet; a, b, line of traction, parallel to axis of inlet; c, f, line of traction with blades inserted at sides of pelvis

The greatest advantage, however, is that the direction of traction can be made more completely in the line of the axis of the brim. With the Tarnier principle it is absolutely necessary to apply the blades laterally; consequently traction is made from the sides of the pelvis. With the antero-posterior forceps the line of traction is downwards and backwards from behind and above the symphysis.

At the time I designed this forceps I thought the idea original, but investigation proved it not

so. Baumers,<sup>14</sup> of Lyons, published in 1849 an article describing a pair of forceps with antero-posterior blades constructed on the same principle. The representations of this forceps depict a very crude instrument having an exaggerated pelvic curve. No effort seems to have been made to modify its construction, although Cazeau found it useful in transverse positions of the head. In such cases, he said,<sup>15</sup> he was "convinced that the biparietal application of the blades, which is impossible with the ordinary forceps, is sometimes easy with that of M. Baumers," and he "thought it right to recommend their application."

Antero-posterior Forceps of Baumers (after Charpentier)

In conclusion I desire briefly to consider the second proposition advanced:

*The obstetrician should not wed any single form or design of instrument, but he should be equally expert with several, and employ one or another, according to the circumstances of the case, always selecting that instrument which best enables him to apply the blades to the sides of the head.*

In direct opposition to this is the statement of some obstetric writers that one form of instrument should be made to answer for all cases. For instance Playfair<sup>16</sup> says: "It is a decided advantage for the practitioner to habituate himself to the use of one instrument, with the application and

power of which he becomes thoroughly familiar. It is a mere waste of space and money for him to incumber himself with a number of instruments of various shapes and sizes, and he may be sure that a good pair of long forceps, such as Simpson's, will be suitable for every emergency, and in any position of the head (italics my own). Simpson<sup>17</sup> and Leishman<sup>18</sup> give similar advice.

In order to obtain an expression of opinion on the subject from the profession in this country, the following question was embodied in the circular letter sent out:

"Do you habitually employ one variety or make of forceps, or do you make use of several varieties?" The replies were divided in this manner: Thirty employed but one variety of forceps, fifty-three used different varieties, and thirty of the latter recognized the value of axis traction in high operations, and eleven used the short forceps in low operations.

Of the class that use one instrument for all cases the Hodge is the favorite; next in order come the Simpson and Elliott

Of the fifty-three who use different styles of long double curved forceps the Hodge is still the favorite, the Elliott next, and then the Simpson.

Of the thirty who favor axis traction for high operations this peculiarity is noted: Only two use the Hodge for ordinary cases, while the Simpson and Elliott are very popular.

With the desire to formulate special indications for the use of different forceps, the question was asked those who used a variety of styles, under what conditions they employed one or another instrument. Some were guided by no rule, and replied: "If one won't answer, try another;" "use the one that seems to be best suited for the case;" "often change from one kind to another;" and one gentleman uses them "just as he picks them up in his office or residence."

The indications for axis traction and short forceps are fully recognized by those who employ the classic double curved forceps for ordinary cases. The selection of the variety of the latter instrument is guided chiefly by its compressive power. Those who advocate the application of the blades to the sides of the head select usually the Hodge, Wallace or Davis. The followers of the opposite method employ the Simpson or Elliott. Other indications noted were the use of Taylor's narrow-bladed forceps in the class of cases for which it is designed; straight forceps for rotation of low posterior positions, and forceps with long, straight, or nearly straight, blades for application to the sides of the head when high and transverse. By one correspondent the short forceps is employed when the head is at the outlet, to regulate its movements and save the peri-

<sup>14</sup> "Gaz. Med. de Paris," 1849, 18. iv. pp. 538-558.

Antero-posterior forceps were also designed by Tytterhoven in 1805. In the discussion of Dr. Sloan's paper Dr. W. L. Reid, of Glasgow, exhibited a pair of antero-posterior forceps which he stated he had used with satisfactory results for seven or eight years.

<sup>15</sup> "System of Midwifery," 3d Am. edit., H. C. Lea, Philadelphia, 1880, p. 468.

<sup>16</sup> Ibid.

<sup>17</sup> "Obstetrical Works, Vol. —, p. 442.

<sup>18</sup> "System of Midwifery," 2d Am. edit., H. C. Lea, Philadelphia, 1875, p. 499.

neum. Two distinguished operators state they always apply the blades to the biparietal diameter, when possible, and they use the Davis forceps. When, from any cause, the blades cannot be adjusted to the sides of the head, they are applied at the sides of the pelvis; but under these circumstances both of the gentlemen wisely discard the Davis forceps; one substitutes the Simpson, and the other the Simpson or Tarnier. There were numerous exceptions to the above rules; for instance, one gentleman, emphatic in his expression of the value of applying the blades to the sides of the pelvis, uses a strong French forceps, the tips of which meet, and the greatest distance between the blades is  $2\frac{1}{4}$  inches.

The comparative compressive power of different styles of forceps is recognized by a number of operators, who employ one or another under conditions which do or do not require that action. One correspondent states that in ordinary cases, as uterine inertia, he uses the Simpson forceps; in pelvic or cranial disproportion, when some compression is necessary, the Elliot; in greater narrowing, but above the limit where craniotomy is to be considered, the Hodge or Wallace.

Another employs the Simpson forceps in first and second positions of the vertex, the Tarnier in third and fourth, and the short forceps when the head is low.

According to the views here expressed, the only conditions generally recognized for selecting the different varieties of forceps are:

- 1st. The high or low situation of the head, and
- 2d. The compressive power of the instrument.

Accepting the opinion of the majority of replies to the circular letters regarding the advisability of applying the blades to the sides of the head when possible, and recognizing the difficulties in the way of accomplishing it in many cases, a third indication advanced is the oblique and transverse positions of the head, for which, and to overcome the difficulties mentioned, I submit the antero-posterior forceps curved on the flat.

In reply to objections made on the ground that this would unnecessarily complicate the armamentarium of the obstetric operator, I would ask to consider one moment whether it is unnecessary.

Does not the dentist possess a number of forceps, curved on the flat and edge, and in all conceivable angles, and does he not select that instrument which best enables him to seize and extract the tooth? He is guided in the selection of the forceps by the position of the tooth, and chooses the instrument that is curved in proper manner to grasp it most securely. Is the responsibility of the obstetrician less than that of the dentist? Is it not incumbent upon him to ascertain positively, in every case requiring artificial delivery with forceps, the position of the head and to adjust the forceps in such manner that he

can extract it according to the natural mechanism of labor.

With the aid of anaesthesia and the whole hand, if necessary, introduced within the vagina, no excuse exists for failure to clear up any doubt regarding the position.

Let me repeat what is stated in the beginning of this communication: "Labor is absolutely a physical act, accomplished according to a well defined mechanism; therefore, the laws governing the application of artificial aid should be precise and absolute." Only until these laws are established and followed will there exist a uniformity of practice in the use of the forceps.

The advice of eminent obstetricians that one pair of forceps should be made to answer for all operations has had, and still has, its evil influence. In no other operation, and in no other special work, is the operator hampered by such advice.

The surgeon has forceps, scissors, knives and needles curved at different angles on both the flat and edge, and he uses them to the best advantage. Why not tell him to discard all these, as they unnecessarily complicate *his* armamentarium? Tell him that one of each, with a proper curve, will answer for all of his operations, and he should learn to employ it only. I claim it equally unscientific to bind the obstetrician to a single pair of forceps, with which he must accustom himself to do all this class of work; and I repeat, "he should be equally expert with several, and employ one or another, according to the circumstances of the case, always selecting that instrument which best enables him to apply the blades to the sides of the head."

## THE CHOICE OF OPERATION FOR STONE IN THE BLADDER.

*Read in the Section of Surgery and Anatomy, at the Fortieth Annual Meeting of the American Medical Association, June, 1880.*

BY A. T. CABOT, A.M., M.D.,  
OF BOSTON, MASS.

In order to make the drift of this paper at once clear, I wish to state at the outset the conclusions I have reached by a study of the results of others in stone operations, and from the moderate experience I have had in these cases myself. Unfortunately, residence in a region where stone in the bladder is rather rare has made the accumulation of personal observations slow, but, on the other hand, my association with Dr. Bigelow has given me unusual advantages in getting an understanding of the operation which he devised and christened "litholapaxy," and of which I shall especially speak to-day.

In my opinion, we have in litholapaxy the operation of choice for the removal of most stones. While this is the rule, there are exceptions to it,

and the varying conditions surrounding stone in the bladder, will now and then lead us to choose some other operation for their safest removal. The surgeon who best appreciates these varying conditions, and selects in each case the operation which most surely avoids the dangers surrounding it, will arrive at better results than any advocate of a special operation, however expert.

I realize that some objections have been urged against litholapaxy, and that superior advantages have been claimed for other methods of stone removal. I shall try to fairly consider these objections, and to justly appreciate the strong points of other operations. Before entering seriously upon our subject, I wish to note one of these objections which seems to me to merit no extended consideration, but which has received a certain amount of weight from the unsupported assertions of some of the German surgeons. It has been urged by them that litholapaxy requires a special skill for its performance, and should not, therefore, be commonly employed. Certainly, none but qualified surgeons should undertake any operation for stone in the bladder, and it seems to me that the question to be discussed is, not which operation is safest in the hands of a tyro, but rather this: By what use of the different methods of stone removal can a competent surgeon accomplish the best results? In modern surgery the test of merit is looked for in results. No operation, however brilliant, can claim superiority over rival methods if its death-rate is much higher than theirs. The best operation is the one that saves the most patients, unless some serious interference with bodily function more than counterbalances the gain in safety.

Let us examine the results of the various operations for stone, in respect to their rates of mortality, their interference with bodily function, and the completeness of cure which follows them. We have, in general, three methods of operation to choose among, namely: perineal lithotomy, suprapubic lithotomy, and litholapaxy. Perineal lithotomy may be again subdivided into median and lateral lithotomy. We have here several wholly different methods, each of which has certain advantages over the others and each of which, on the other hand, has its own difficulties and dangers, to be recognized and avoided. The cases for which these operations are to be considered and selected, also differ vastly in their conditions and complicating surroundings, so that it may well be seen that each case should be studied for itself, and the operation chosen which best meets the difficulties and avoids the dangers present in that particular instance.

First, looking at the rates of mortality obtained by these operations, we find at once that we cannot properly compare the results in patients of very different ages. The mortality in children and young adults, after any operation upon the

bladder, is distinctly less than it is in advanced age, and, as we shall see later, there are at different ages changes in the organs concerned which make marked differences in the manner in which the various operative measures are borne. For the sake of convenience in this study, cases may be grouped in three categories:

Children, from birth to 14 years of age.

Adults, from 14 to 50.

Old men, from 50 upwards.

This division of the cases is somewhat arbitrary, but the ages of 14 and 50 are selected as marking, more or less accurately, certain epochs in the development and decay of the genito-urinary organs. At about 14 we look for the changes in the size and sensibility of these organs which accompany the arrival at puberty; and at 50, senile changes in the prostate and bladder begin to make their appearance, which often interfere seriously with the healthy performance of the functions of those parts. In the collection of statistics those tables have been used in which operators have published all of their results, and reports of single cases are not included. This is done to avoid the danger of forming tables of exceptional results; for single cases are more likely to be reported when successful than when they resulted unfavorably. Further, owing to the recent improvements in technique and to the influence which the general adoption of antiseptic measures has had upon surgical diseases, it is evident that the statistics of old times cannot be accepted in settling the present status of these operations; and, therefore, only cases occurring since modern methods came into vogue have been used in this study.

SUPRA-PUBIC LITHOTOMY

Operator or Reporter.	Children				Adults				Old Men.

- Seven fistulae.

Freyer gives the following rates of mortality after lateral lithotomy, arranged according to age. They are calculated from 987 cases occurring during the year 1883 in the Northwest provinces of India:

Rate of mortality up to 20 years	5.1 per cent.
" " " from 20 to 40 "	10.7 " "
" " " above 40 "	31.9 " "

Rosenthal, from a collection of 400 cases, deduces the following rates.

Mortality, from 1 to 5 years	3.5 per cent.
" " " 6 to 11 "	2.1 " "
" " " 12 to 16 "	8.4 " "
" " " 17 to 29 "	15.7 " "
" " " 30 to 66 "	38.8 " "

These statistics probably give a more accurate rate of mortality for old men than in my table, in which so few cases occur at that time of life.

From these statistics we see that in childhood, judging from the results as to mortality, there is little to choose between lateral lithotomy and litholapaxy. The death-rate in each is but little over 3 per cent. Suprapubic lithotomy is more dangerous, with a death-rate of about 10 per cent. In adult life, the death-rates alter somewhat in favor of litholapaxy. As the prostate and urethra enlarge, and the parts about the neck of the bladder become more vascular, the dangers incident to cutting through them increase. On the

other hand, the increase in the size of the parts makes the performance of litholapaxy comparatively easy and safe. Suprapubic lithotomy keeps its place as a more dangerous operation than either. In old age the rates of mortality are overwhelmingly in favor of litholapaxy. While the dangers attending all the cutting operations have increased very greatly, the mortality after crushing is very little higher than it was earlier in life.

## INTERFERENCE WITH THE FUNCTION OF THE PARTS.

It is somewhat exceptional to see a serious loss of function follow any of the operations for the removal of stone. A litholapaxy, carefully performed, should never cause any lasting injury of the genito-urinary organs. The suprapubic incision rarely causes any after-trouble, although occasionally a fistulous opening remains which cannot be closed, and is therefore a constant source of discomfort to the patient. The perineal operations, entering as they do through the neck of the bladder, are much more likely to cause serious trouble. The position of the seminal ducts in the lower part of the prostate, makes their injury by an incision in the floor of the prostatic urethra quite probable. The median operations may sometimes avoid this when the stone is small enough to be removed by stretching the neck of the bladder, but even then lacerations are likely to occur. The lateral incision has the advantage that, while giving more room, it endangers only one of the ducts. The erectile tissue, known as the caput gallinaginis, is also liable to injury, and this may cause sterility. Incontinence is an occasional result of the perineal incisions, owing to their interference with both of the sphincters of the bladder; and fistulae, though rare, do sometimes occur, and may be very persistent and troublesome. Injuries of the rectum during lateral lithotomy are unnecessary and accidental; they still happen often enough in the hands of expert operators, to make it worth while to take the chance of this into account in deciding upon an operation.

## COMPLETENESS OF CURE.

It is a not uncommon experience to see a second or a third attack of stone in the same patient. In order to understand how far this reappearance of a calculus is dependent upon the operation by which its predecessor was removed, let us consider the ways in which a recurrence of stone may come about.

1. A uric acid stone may be followed by another, on account of the persistence or reappearance of the uric acid diathesis. The same may be true, though less commonly, in the case of an oxalic stone, and may even occur with a phosphatic stone due to phosphaturia of constitutional origin.

2. The successive escape of several stones from

the kidneys may give rise to several consecutive attacks of stone in the bladder. These stones may be uric, oxalic or phosphatic.

3. A soft, phosphatic stone may be reproduced after removal, if the chronic cystitis and alkaline condition of the urine, which led to its original formation, persists. This is not uncommonly seen in those cases where an obstruction to the complete emptying of the bladder perpetuates the fermentation of the urine.

4. Lastly, if a fragment is left after an operation, it may serve as a nucleus for another stone. The danger of this mischance is greatly increased by any obstruction to the flow of urine, such as is caused by an enlarged prostate. The bladder, in such a case, is often sacculated, so that fragments are more likely to escape removal by the evacuator after litholapaxy, or by the lithotomy scoop and forceps after lithotomy; and if such a fragment be left, it is very unlikely to be voided by the natural efforts of the bladder, but remains in the residual urine. A healthy bladder that completely expels the urine at each act of micturition usually frees itself of such small fragments.

It is plain that recurrences due to the patient's diathesis, in which a new stone forms years after the removal of a former one, cannot be laid at the door of the operation, being as likely to follow one method of removal as another. And the same is true when successive escapes of renal calculi from the kidneys give rise to recurrent attacks of stone. Among my cases, 47 in number, I have seen three instances of the recurrence of uric acid stone due to the patient's diathesis, and have had one case in which calculi of renal origin gave rise to successive attacks of stone in the bladder.

Next, we have the cases in which a recurrence is due to a persistent cystitis with consequent deposition of phosphatic material. I have seen four instances of this sort, all of them occurring in patients with greatly enlarged prostates, and in all of which I was able to satisfy myself conclusively that the recurrence was not due to the retention of fragments. In such cases, the later attacks of stone cannot be ascribed to incompleteness in the operation, but rather to neglect in the after-treatment.

It is important that to prevent this sort of recurrence, it is important to entirely relieve the cystitis before allowing the patient to pass from observation, and then to send him away with a clear understanding of the importance of immediately correcting any tendency to alkalinity of the urine or to pus formation. When an obstructed urethra is the cause of the cystitis, the obstruction should be relieved if possible. In case of an enlarged prostate, the evils of retained urine must be lessened as far as possible by systematic catheterization. The moment that any considerable amount of mucus or other evidence of commencing fermentation appears in the urine

of one of these patients, thorough irrigation of the bladder must be instituted and kept up until the normal condition is again reached. If milder measures fail to keep the urine in a fairly good condition, or if the catheter causes pain and has to be used very frequently, a prostatotomy may be called for to correct the obstructing condition. It may sometimes seem well in these cases, if the stone is a small one, to remove it by a perineal incision, for the sake of the opportunity to at the same time operate on the prostate and to drain the bladder. Dr. J. P. Bryson, of St. Louis, has called attention to this occasional advantage of a perineal operation for stone. A surgeon selecting such an operation should, however, bear in mind that the perineal operation is about three times more dangerous to life than litholapaxy, and should balance the hoped-for advantage against this certain risk. In one such case, the writer did a combined litholapaxy and prostatotomy: first crushing and pumping out the stone, and then, through a median incision, dividing the middle lobe of the prostate. The operation was no more severe than a simple prostatotomy, and the power of urination, which had been absolutely lost, was restored to a very considerable extent.

Finally, a stone which has for its nucleus a fragment of an earlier stone is obviously the result of an incomplete operation, and it has been urged against litholapaxy that such recurrences are especially liable to take place after it.

In the early days of this operation such instances of incomplete evacuation were more common than now, and were due to a want of thoroughness in the surgeons rather than to a necessary lack of completeness in the operation itself. To guard against such retention of fragments, many operators now make it a rule to always wash the bladder once or twice with the evacuator some days after the operation, before the patient is discharged. These washings cause but little discomfort, and may usually be done without anesthesia. These washings, if successful in obtaining debris, should be continued at intervals of a few days until fragments are no longer obtained, and in cases of cystitis, where the tendency to the deposition of phosphates is very great, it is a good plan to give an occasional wash with the evacuator up to the time that the urine becomes clear and loses its alkalinity. In using the pump at the time of operation, and in these subsequent washings, the sacculated character of many of these bladders should be borne in mind, and a careful search should be made for fragments which may be caught in pockets. The orifice of the evacuating tube should be turned successively toward each part of the cavity, to dislodge with the current all such fragments, and, lastly, the pouch which so often exists behind the prostate should be searched in this way. For these manœuvres a straight tube is especially adapted and

should, when possible, be used. With a careful observance of these precautions, I confidently believe that a retention of fragments after litholapaxy need be of no more frequent occurrence than after lithotomy. Indeed, it has happened that fragments left by lithotomy have been subsequently removed by the litholapaxy pump.

#### SELECTION OF OPERATION.

*In Childhood.*—As the statistics show, the mortality after any operation for stone in children is small. Lateral lithotomy and litholapaxy are very nearly equal in this regard, and both are decidedly safer than suprapubic lithotomy. The crushing operation has the great advantage that it avoids injury to the seminal ducts and the rectum; also that it does not give rise to fistula or to incontinence of urine; all of which are occasional results of perineal lithotomy. An ample experience has shown that the urethra and bladder of a child will tolerate a considerable amount of instrumentation. It would therefore seem wise to use litholapaxy for all small stones or stones of moderate size (from 1 and  $1\frac{1}{2}$  to 2 centimetres in diameter), and for stones larger than this to do lateral lithotomy, except when they are very large ( $3\frac{1}{2}$  centimetres and upward in diameter), and then suprapubic cystotomy is to be resorted to.

The ease with which bimanual palpation can be practiced in children, with a finger in the rectum and a hand on the abdomen, makes it possible to judge, pretty closely, the size of the stone, and so to select intelligently the best operation for its removal. The consistency of a stone is also to be taken into account when litholapaxy is thought of, and stones of considerably larger size than is above indicated may properly be crushed if they are soft and friable. The quality of a stone in these regards may usually be determined with some degree of accuracy by the sensation imparted to the sound and by a knowledge of its probable constituents, which can often be gained by an examination of the urine. Phosphatic stones are usually soft, as are also pure uric acid stones. The urates make a rather hard calculus, while an oxalic stone is exceedingly hard and resistant. Certain other conditions which would lead us to employ some other method than litholapaxy will be spoken of in considering operations on adults.

*In Adults.*—Whether we consider the danger of the various operations for stone in the adult, or the likelihood of disturbance of function following them, we are led to regard litholapaxy as the operation of choice for stone removal. With the efficient lithotrites and evacuator which made "lithotripsy at one sitting" possible, it is now usual to remove stones of considerable size and hardness, and practically it has been found that under ordinary conditions in adults, any stone which is suitable for lateral or other perineal lith-

otomy is suitable for litholapaxy, and that even stones so large that they would require a suprapubic incision if they were removed by the knife, may, when reasonably friable, be safely crushed and pumped out. A number of instances are on record in which stones between 2,000 and 3,000 grains in weight have been successfully removed in this manner.

The exceptional cases in which litholapaxy cannot be used are as follows:

1. A very large and hard stone may resist every attempt at crushing, especially if it is tightly grasped by the spasmodically contracted bladder.

2. A stone may have as a nucleus a foreign body such as a piece of necrosed bone or a bullet, too hard to crush and too large to pass out through a tube.

3. An encysted stone may be out of reach of the lithotrite.

4. Some writers hold that stricture of the urethra may prohibit litholapaxy. This cannot often happen, for strictures, however close, yield readily to division, which may immediately be followed by the crushing and evacuation of the stone. I have so often seen these two operations successfully done together on an etherized patient, that I can but think this the best practice. While it economizes time, it saves the patient much needless manipulation.

5. False passages may exist, which so interfere with the introduction of instruments that the dangers of the operation are greatly enhanced, and the question of lithotomy is to be entertained.

6. The hip may be ankylosed in a position which interferes with the use of urethral instruments.

7. A stone may be so lodged in the entrance to the urethra, that it cannot be pushed back into the bladder where it can be seized by the lithotrite.

In any of these exceptional cases in which litholapaxy cannot be applied, we have to make our choice between a perineal and a suprapubic incision. The danger attaching to the perineal incision is, according to present indications, decidedly less than that after the high operation, so long as it is applied to small or medium-sized stones; but when large stones are dealt with, the facts are reversed, and the perineal operation becomes the more dangerous of the two. Under ordinary circumstances, as has been said, litholapaxy disposes of the stones of a size suited to perineal removal, and these operations through the perineum have therefore fallen largely into disuse for adult cases. They find occasional application in cases of stones of moderate size where false passages, ankylosis of the hip or the presence of a foreign body make litholapaxy impossible. They may also be used rarely when severe obstructive disease of the prostate makes it desirable to combine prostatotomy with the operation for the removal of the stone. A stone impacted in the neck of the bladder, if it

cannot be dislodged, may properly be removed through the perineum.

Suprapubic lithotomy is to be employed in cases where the stone is too hard and large to be crushed, or where an impervious urethra makes the introduction of a lithotrite or staff impossible. In case of an encysted stone the high operation is also the best, as the thorough inspection of the bladder which it makes possible enables us to treat the condition intelligently. Occasionally, cases are met with in which the prostate is so large that the bladder cannot be reached through the perineum, and here, of course, one is driven to do a high operation if a stone exists which it is not possible to crush.

*In Old Age.*—The same indications are to be followed as in the adult, except that it is to be remembered that perineal incisions are especially dangerous in old men, and not to be undertaken for the removal of stone without urgent reasons. The suprapubic operation will therefore be called upon to deal with most of the stones which are unsuitable for litholapaxy, and even with this incision, a prostatotomy or prostatectomy may be done after the removal of the stone if the conditions require it. As was seen by the statistical tables, it is in old men that the crushing operation has the most unmistakable advantage. The urethra and bladder, in old age, are very tolerant of the use of instruments, so that litholapaxy is ordinarily well borne.

In conclusion, I wish to say a few words about my own experience with stone operations. I have operated forty-seven times, selecting the operation in each case according to the principles I have set forth above. There were forty-two litholapaxies, nine of them in adults and thirty-three in old men; three lateral lithotomies, all in children; one median lithotomy in an old man and one suprapubic lithotomy in an adult.

Of the cases of lateral lithotomy, two were done before it was believed possible to do litholapaxy in children. In the third case there were two stones, one of which was firmly fixed in the prostatic and membranous urethra. The median lithotomy was done for a small stone impacted in the prostatic sinus, and the suprapubic operation was done for a large, hard stone, in a patient having a bad stricture of the urethra with false passages about it. Among these cases there were three deaths; two following litholapaxy and one after median lithotomy. Of the cause of death in these cases I wish to speak briefly.

*Case 1* was a broken-down man of 69, for whom litholapaxy was done for a phosphatic stone weighing 98 grs. The operation went smoothly and the relief from it was complete. The urine cleared up and, after a few days, was passed normally without pain or frequency. In short, he made a perfect recovery from the operation. On the fourth day a chronic bronchitis that he had had

before entering the hospital became much aggravated, led to pneumonia and of this he died on the ninth day.

*Case 2* was a patient 71 years of age, whom I saw at Bennington, Vt., August 24, 1887, in consultation with Dr. Leroy McLean, of Troy, N. Y., and Dr. Jennings and others of Bennington. He had had trouble with his bladder for three or four years, but had been able to keep about with it till eight days before I saw him, when he had suddenly been seized with an acute exacerbation of cystitis with retention, for which the bladder was aspirated over the pubes. During one of the aspirations the needle touched a stone. When I saw him he was suffering from great pain and frequent painful tenesmus; his pulse was rapid and weak, his countenance smken. The urine, which had been abundant at first, had almost ceased during the past twenty-four hours. The general feeling at the consultation was that the patient was in a dying condition, and that any operation could only be looked upon as a last effort to give him some more chances of recovery. With this understanding litholapaxy was undertaken. The bladder contained 2 or 3 ozs. of thick, bloody mucus, with almost no urine. The stone was very hard (oxalic), and weighed 1 oz. The operation was a long one. After the stone was out, a catheter was tied in the bladder. There was no reëstablishment of the flow of urine and the patient died on the following day.

In the first case death was due to a pneumonia, and the bladder and kidneys were in good order. In this series of forty-two litholapaxies we have, then, but one death due to the condition of the urinary organs, and even that could not fairly be ascribed to the operation. Among the successful cases were several in which there was distinct evidence of an already existing interstitial nephritis, and yet the patients bore the operation well.

*Case 3.*—The third death occurred also in an old man (over 70 years of age), broken down by hard labor as a missionary in the tropics, who had just recovered from a severe illness on his voyage home. He had a small stone lodged in the prostatic sinus, which caused much pain with frequent micturition. This stone was removed by a median perineal incision and at the same time the third lobe of the prostate was divided with a probe-pointed bistoury. A drainage tube was fastened in. After doing well for a few days he gradually developed a septic condition of the wound which, in his enfeebled condition, proved fatal. This was the only case in the series of forty-seven, in which the fatal issue was distinctly the result of the operation.

## SUMMER DIARRHŒA AND DYSENTERY IN CHILDREN.

*Read by title in the Section of Diseases of Children at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY N. GUHMAN, M.D.,

OF ST. LOUIS, MO

Before I commence to read my paper I will ask your patience and indulgence if I wander somewhat from the title. I think the propriety of the digression will be apparent before I conclude.

During the summer months you are all aware of the prevalence of diarrhœa, dysentery and disturbances of the gastro-intestinal canal. I will not take up your time in giving definitions of the terms, or in detailing the pathological and physiological changes which occur in the digestive organs in these diseases, as you will find these stated much better in your text-books than I can describe them to you. What are its causes? Atmospheric changes, heat, rainy and sultry weather, warm during the day and cold at night, impure air and water, insufficient clothing, a badly nourished, fretful and overworked mother or wet-nurse, imprudence on the part of the mother or wet-nurse in the selection of food and drink, over and too frequent feeding of indigestible food, or cooked food which has been kept too long, perhaps in a patent unclean nursing bottle, with a rubber or glass tube attached to it, or which has been kept in an ice-box with various kinds of vegetables, meats, cheese and butter. I suppose most of you have drunk milk or water or eaten butter which had been kept in an ice-box in which strawberries, raspberries or canteloupes had been stored away to be kept cool until used, and no doubt all of you have noticed the effect of placing such articles in the same ice-box. I look upon ice-boxes, in which there are placed all sorts of decomposing and fermenting articles, such as we generally keep for our table use, as breeding boxes of bacteria and microbes and all kinds of germs. Of course I am aware that we cannot have a separate ice-box for each kind of food we eat. Another point to which I desire to call your attention is the use of ice in drinking water. We should not put the ice in the water we drink. It is far preferable and less dangerous to cool the water by keeping it near the ice. You all know that all the ice is not as pure and clean as it should be. Ice-boxes need ventilation and the use of care in selecting the articles which are placed in them as much as our dwellings. These points may be foreign to the title of my paper, but I consider them very important points for us to remember. I have no doubt that bacteria and microbes play an important part in these diseases.

Is dentition of children the only cause of diarrhœa and dysentery during the summer season? I doubt it. During the winter months the mothers come to your office with their babies and say:

"My baby has a cold and the snuffles;" and during the summer, "dentition;" so that in summer they ascribe the trouble of dentition to diarrhœa, and in winter to diseases of the respiratory organs. The question may be asked, may not the irritable and swollen condition of the gums, which we see existing in some children, cause diarrhœa through a reflex action of the nervous system? If you take notice you will see that this condition of the gums occurs only where a child is broken down more or less from diarrhœa and deficient assimilation of food. You do not observe it in healthy children.

What are the varieties, symptoms and character of summer diarrhœas and dysenteries, simple and inflammatory or dysenteric diarrhœa? The above mentioned causes may produce either of these troubles; it all depends on circumstances—in which direction it strikes. It may produce cholera infantum under certain conditions. I think these diseases are closely allied to each other. In the beginning of the attack we first observe vomiting of indigestible food, curdled and cheesy milk. I suppose many of you have seen children vomiting a white coagulated mass of cheesy material, tough like rubber, elongated and moulded by the œsophagus as long and thick as a thumb. It seems to me it would take some time for the formation of such a mass, and much longer to expel it from the stomach. The physician should be very careful not to make a mistake when he is called to a child which is vomiting, or an empty retching symptomatic of, caused by, or a forerunner of cerebro meningitis or other brain lesion, where the former is caused by local irritation and the vomiting is easy, with very little straining, while in the latter the effort of vomiting is preceded by a little hacking cough and retching, with vomiting of a little mucus or a yellowish-green fluid, although you may have the same condition in acute gastritis; during vomiting or immediately afterwards you have an action of the bowels of indigestible food and faecal matter of a more or less thin white, grayish color, curdled and of an acid odor; or the discharges from the bowels may be of a greenish color, intermixed with white lumps, casein; and then at last comes the dysenteric form, tenesmus, with a little mucus and streaks of blood, or a yellowish, slimy mucus, with some faecal matter and blood of an offensive odor. At this point I would draw your attention to cases which may occur in summer as well as in winter, where the child lies on its back, legs drawn up, with a continued straining, and passing nothing but red blood, mixed with a little mucus and no faecal matter, and with scarcely any odor. What might we expect in such a case? Probably an inversion or intussusception of the large or small bowel. It may be near the rectum, or higher up. If it is in the lower part of the bowel, we may be able, by a digital examination,

to feel the inverted bowel in the lower part of the colon; if higher up, we might make our diagnosis with a flexible catheter or bougie, and if we are in doubt about our diagnosis I would give the doubt the benefit.

What would be the treatment in such a case? First elevate the child's pelvis so as to favor gravitation towards the diaphragm and chest, and fill up the bowels with warm starch water, with a long or short flexible tube attached to a fountain syringe, according to the location of the obstruction, whether low or high up, or the inflation of air. If this is not successful I would advise laparotomy, the same as in a grown person. I do not know why the operation should not be performed as well in a child as in an older person, although laparotomy is not often performed in children under such circumstances. We all know that a child in such a condition will die if not relieved, and I do not see why laparotomy is not as justifiable as tracheotomy in obstruction of the larynx.

What treatment should we follow in case of diarrhœa and dysenteric diarrhœa? First remove the cause and make correction in the food and drinks. Do not overload the stomach. Let the child have plenty of fresh air. Medication should be very simple and mild, such as emollients, demulcents, antacids, antiseptics and peptonoids in some form. Be careful of opiates where you have fever or congestion of the conjunctiva, or the least indication of brain lesion. Astringents should hardly ever be used. I never derived any benefit from them, and I have always regretted their use when I employed them. If the fault is in the secretions, small doses of hydrargyrum cum creta or chloridum mite with lactopeptine, which will promote and stimulate the secretions of the digestive organs. If the diarrhœa is of an acid odor, diluted lime water, bicarbonate of soda with the chalk mixture; and if there is any indication for an antiseptic I add some listerine, carbolic acid or creosote. In inflammatory or dysenteric diarrhœa, if the stools are greenish, slimy, mixed with mucus and accompanied or preceded with pain and tenesmus, my favorite remedy is lactopeptine added to a castor oil emulsion, with a little paregoric or McMan's elixir of opium, if not contra-indicated, warm cloths or hop and flaxseed poultices to the abdomen. I always give my little patients enough to drink. I instruct the nurse to get a large piece of ice, wrapped in a blanket, put it in a large dish and keep it in the sick-room, so as not to require them to run up and down stairs to the clean ice-box, which I have described before. I order the medicine, if it is fluid, lime water, some good whisky or brandy, also a soda bottleful of rice, gum arabic and barley water in the dish near the ice, to keep it cool. I always make it a rule, if possible, to look at the stools before I prescribe.

If they come to my office, I require them to bring the last two diapers with them. I prefer to look at them myself, rather than get an imperfect description from the mother or nurse. They will not tell you of the indigestible food, such as potatoes, meat, apples and all kinds of seeds from fruits. They very readily tell you the child is no better, and the medicine did not do any good. Hold up the diaper and ask the mother if she carried out your instructions. Of course she will excuse herself—say that the child picked it up from the table, or got it from its little brothers or sisters.

Gentlemen, you are all aware that we have not so many cases of summer diarrhœas and dysenteries, or any other disease, now as we had in former times. Why? Because the public is better educated in hygienics, they occupy better houses and more room, our cities are better sewered and drained, and sanitation is better in our large cities than elsewhere. There is more cleanliness all around.

Since writing my paper I read the report made by Dr. Henry Tomkins before the British Medical Association in Glasgow, on bacteriological researches in connection with summer diarrhœa, as he had studied it in the town of Leicester, where he resided, and published in the *British Medical Journal*, August 25, 1888. It will be very interesting to all of you and I have no doubt that we will all profit by it, and if the Chairman will allow me to read it I will do so.

*"Bacteriological Researches in Connection With Summer Diarrhœa.*—Dr. Henry Tomkins brought this matter before the British Medical Association at its recent meeting in Glasgow. He alluded more particularly to the subject as he had studied it in the town of Leicester, where he resided (*British Medical Journal*, August 25, 1888.)

"In approaching the subject two facts were to be borne in mind: (1) That all diarrhœas, not some diarrhœas, were often only a symptom of varied morbid conditions, as pointed out at the Cardiff meeting of the British Medical Association by Dr. Vacher; but, after all due allowance made, there undoubtedly remained a large residue of cases of a specific or special nature, constituting a disease *per se*, as much so as true Asiatic cholera; (2) that that disease was not a disease of infancy or early childhood only, or even for the greater part. Exact observation showed that the bulk of sufferers from it where it prevailed were of more mature years, though, owing to the mortality occurring almost exclusively amongst young children, this fact had often been overlooked. Of all English towns Leicester was, par excellence, the home of this disease, if its mortality was to be taken as a true criterion of its prevalence. During the past three years, since holding the office of Medical Officer of Health there, Dr. Tomkins had paid special attention to the

subject. It was easy to disprove that many of the reputed cases gave no satisfactory explanation of the disease. Many of these affect only the infantile population, and affect these more or less throughout the whole town, whereas the prevalence of the disease was confined to certain well defined low-lying districts of the town and affected all ages and occupations, etc., within those districts. The cause must be something common to every resident within those districts, which something was apparently absent in other parts of the borough. The only things or conditions common to all were food supplies, water and air. The two former were the same throughout the whole town; there remained, therefore, only the air. During the past three years Dr. Tomkins had undertaken a large series of observations on the air, with special reference to the microbic forms of life contained therein. The general result showed that the air of the diarrhoea district of the town contained three to six times as many microorganisms and their germs as the air of the non-affected districts. These microbes (or certain of them) grew in a distinctive manner when artificially cultivated, and were capable of producing diarrhoea; or, perhaps more correctly speaking, the products of their artificial cultivation were capable of producing diarrhoea in the human subject. At present Dr. Tomkins was endeavoring to isolate and single out the particular form or forms which were most concerned in this. The organisms and growths obtained from various tissues, organs and intestines in fatal cases of diarrhoea give like results. A very probable explanation of the undue prevalence of diarrhoea in Leicester, or rather in certain parts of the town, was found in this excess of aerial microbes and germs, and this excess might be satisfactorily accounted for in the following way: Since 1850 (from which date the prevalence of diarrhoea appeared to have commenced and increased) the whole of the area of the "diarrhoea district" of the town had been subjected to a pollution with organic filth, more or less of an excremental character. This, acted upon by the heat of the summer sun, amply sufficed for an enormous production of bacteria. Imperfect and filthy sewers, containing much deposit, in the same way contributed to like results. Meteorological observations during the summer months of 1885, 1886 and 1887 showed that as soon as the earth, at a depth of one foot, reached about 62° F., the disease broke out. At the time of writing (July 23, 1888) this subsoil temperature had not yet been reached, and the outbreak had not yet commenced for this year. In addition to the need for more exact isolation and identification of the "diarrhoea microbe," it was of equal importance to study how this and other bacteria acted in producing disease; whether it was probable by the production of some poisonous material of an alka-

loid character, such as ptomaines or leucouaines. These inquiries were of supreme importance to the physician and clinical observer, as well as hygienist, but could hardly be expected to be carried on by an ordinary health officer, with multifarious routine duties to attend to. Such questions as these required the whole time and attention of specialists."

## IS SENN'S GAS TEST INFALLIBLE AND ALWAYS DEVOID OF DANGER? TWO CASES OF SHOT WOUNDS. CONCLUSIONS.

*Read before the Mississippi Valley Medical Association, at its meeting at Evansville, Ind., September 11, 1889.*

BY H. C. DALTON, M.D.,  
SUPERINTENDENT CITY HOSPITAL, ST. LOUIS.

I report to-day one case of laparotomy for shot wound, and another in which an operation ought to have been performed, and would have been, had I not been deterred on account of the failure of the Senn method, being led thereby to believe that the intestines were intact. It is not always pleasant to report our failures, but believing it a duty we owe the profession, in order that our statistics may be reliable, I have made it a rule to report all my failures as well as successes in abdominal surgery.

It is true this course may subject me to criticism owing to some sins of omission or commission, but as criticism will teach me wherein I have erred, I shall still be the gainer. Should the criticism be unjust, I trust it will proceed from him only who has never made a mistake in surgery. This apologetic prelude is written to induce you to "be to my faults a little blind," when you listen to the "o'er true tale" of the two following cases:

*Case 1.*—B. J., colored, æt. 35, laborer; admitted to the hospital October 25, 1888; was shot at a distance of twelve or fifteen yards three hours before admission, after which he was unable to walk, and soon felt a numb, dead sensation in the right leg, followed by pain in the abdomen.

Examination showed a shot wound an inch and a half above and a little to the right of the anus, the probe passing upwards and inwards through the great sciatic notch into the pelvic cavity. The urine was drawn and found to be clear. There was absence of liver dulness to the extent of two inches above the border of the ribs. The patient was suffering from shock and intense pain in the abdomen, referred to the umbilicus. The extremities were cold, pulse 72 and respiration 39, rectal temperature 96.6° F.

Assisted by Drs. Meisenbach and N. B. Carson, and the hospital staff, I proceeded to make median laparotomy, using Senn's hydrogen gas test

before making the incision. A small hole was made about two inches below the umbilicus, a glass tube was put in and an ineffectual attempt was made to ignite the gas. When the tube was removed the gas escaped through the hole and ignited readily. Upon enlarging the wound the gas escaped with an audible sound. The bullet was found to have entered to the right of, and almost grazing, the iliac vessels. It then entered the cæcum a little to the inner side of the appendix, and passed out an inch and a half above. Twelve holes were closed by the interrupted Lembert suture, iron-dyed silk being used, two in the cæcum (as described above), six in the small intestine, three in the mesentery, and one—the hole of entrance—near the iliac vessels. The bullet was not found, nor were we able to find it post mortem.

After a thorough peritoneal toilet we attempted to return the enormously gaseous, distended intestines, but found, like Banquo's ghost, that they would not down. It seemed our task was like that of Sisypheus, for as fast as we would replace one coil another would "bob up serenely from below," until our patience, as well as our patient, was well nigh exhausted. To make confusion worse confounded, about this time, when we thought our task almost completed, the intestines being nearly all reduced, two or three sutures gave way and the cavity was again flooded with fecal matter. In the attempt to reduce them the intestines were necessarily subjected to rather rough handling and considerable pressure; hence the rupture. The sutures which gave way were those closing two holes which were very close together, and we found it difficult to locate the exact spot from which the feces escaped. We accomplished it, however, by a very simple, but, I think, important method suggested by Dr. Carson, *i. e.*, allowing water from the irrigator to play upon the part while making pressure upon either side of the holes. The escape of the gas elevated the water to perhaps a half inch, indicating the exact site of rupture. An attempt was made to get rid of the gas by washing out the stomach and putting a cylindrical speculum into the rectum to facilitate the escape of the gas, but this much vaunted method failed utterly.

Here was a case where the Senn method not only did no good, but absolutely did a great deal of harm; but more anon. The case also teaches a valuable lesson in that it should caution us, no matter how far away the wound of entrance may be, to look out for abdominal injury if the range of the bullet be in that direction. In a conversation with Dr. Senn, some weeks ago, I informed him of the above facts. He stated that he had also been annoyed by the same thing, but it could be overcome by elevating the hips and using a large funnel-shaped towel to produce compression upon the intestines during their reduction.

I do not believe that it would have worked in this case.

*Case 2.*—Wong Gau, Chinaman, æt. 25, laundryman, entered the hospital at 7:25 P.M., October 11, 1888. One hour before admission he was shot by a negro at a distance of ten feet, the bullet entering between the fourth and fifth ribs in the left axillary line.

The assistant who examined him (I was absent at the time) probed the wound and concluded that it did not penetrate the abdominal cavity, a very natural mistake, as there were no symptoms pointing in that direction, except that he had vomited several times, the ejecta, however, containing no blood. When I returned to the hospital, three hours after the injury, the pulse had gone up to 100, temperature 100° F., but there was still entire absence of abdominal symptoms. Suspecting, however, from the direction of the bullet, that it had penetrated the cavity, I resected two inches of the seventh rib in order to inspect the diaphragm. A hole was found in the same about three inches from the thoracic wall. Through this hole I placed a glass tube and applied the hydrogen gas test, which gave negative results, although the tube was moved in various directions and removed several times to see if it was unobstructed. The urine was drawn and found to be clear. Having great faith in the gas test I was satisfied that the alimentary canal was intact. My faith has received several rude shocks, and I am no longer an enthusiastic advocate of the measure, except in certain cases. The diaphragmatic and thoracic wounds were closed with heavy chromotized catgut. Patient died twenty-eight hours after the injury.

The above cut shows the relation of the food and bullet holes to the stomach as revealed by the autopsy in Case 2. The arrows show the course the gas would naturally take in passing up the alimentary canal rather than to displace the food sufficiently to gain exit through the bullet holes.

The autopsy revealed two holes in the stomach and a large lacerated wound of the left kidney. The holes were on the greater curvature, three or four inches below the cardia. They were quite close together (half an inch of septum), each

hole being about half an inch in diameter. The stomach was one-third full of semi-solid food, mostly rice, the consistence of which was so firm that it failed to run out when the stomach was elevated, nor did any escape ante-mortem. The food plugging up the holes and overlying them, accounts for the failure of the gas to escape. It naturally sought the higher and unobstructed portion of the stomach, and by its pressure plugged up the holes still more securely.

During anæsthesia the patient came near dying from interference with respiration, due to the great gaseous pressure upon the diaphragm. Had there not been large gaseous eructations, partially relieving the pressure, I believe he would have died upon the table. The case teaches that extreme care should be taken in giving the anæsthetic during the gas test. It also teaches that the test is liable to deceive us at a very important juncture, and that we cannot positively depend upon it in gunshot wounds.

In the above case I might have turned the patient on the right side allowing the food to gravitate to the right, leaving the holes free for the exit of the gas. But who would have suspected such a condition as we found in the case, or would have thought of the necessity of placing the patient in such various positions? It is certainly unusual to have a patient with both stomach and kidney so badly injured without some blood being vomited, or being found in the urine, and this assisted the Senn test to deceive us in the case. I object to the use of the gas test in shot wounds for the following reasons:

1. Because it is misleading, not being *always* reliable.

2. Because even if it give negative results, we should operate anyway, as we are not sure that the intestines are not perforated, and statistics give but poor encouragement to those who adopt the do-nothing plan, the recoveries in such cases being less than 8 per cent.

3. Because even were we positive the intestines were uninjured, there are other organs which are almost equally important, such as the liver, spleen, mesentery, etc., which might require prompt attention.

4. Because I believe there is danger of the gas forcing fæces through the wounds into the peritoneal cavity, thereby adding to the gravity of the case. It is said this does not take place, but I am loath to believe it.

5. Because of the additional danger during anæsthesia from interference with respiration.

6. Because of the liability of the sutured holes to be torn open while handling the intestines, especially during the effort to return them to the peritoneal cavity, as in case 1.

7. Because after their return to the cavity, owing to their distended condition, and the consequent pressure upon the diaphragm, it em-

barrasses respiration, and hence adds to the shock. I believe this to be a valid and most serious objection to its use. He who can put his patient to bed with the least shock, *ceteris paribus*, has the best chance of seeing him recover, for shock is the cause of death in the vast majority of cases; and certainly the liability to death during anæsthesia, while not probable is more likely to occur with the use of the gas than without it, and hence should be taken into account.

Those who have attempted to close the abdomen over intestines distended by gas can fully appreciate my statement. I imagine that a well person with intestines so distended would suffer from colic, and a feeling of oppression consequent upon the great gaseous distention. Why should we add such additional danger to our patient, already in such a perilous condition, when a feather's weight may turn the scale against him? It may be claimed, and I grant it, that the gas soon becomes absorbed, but why subject a patient to an additional risk, even for a short time, at such a critical period? Then too, the preparation and administration of the gas takes up valuable time, it is true not a great deal of time, but when one remembers that the saving of every moment in these cases is vitally important, he naturally is anxious to get through at the earliest moment consistent with the proper management of the case.

Senn reports a case of shot wound of the intestines in which, after sewing up all the holes he could discover, he was enabled by the use of the gas to find another, low down in the rectum, which he could not have found without it. I imagine such cases are very rare, and do not counterbalance the harm which the gas may do in other directions. I would not leave the inference that I have discarded the gas test. I would use it in shot wounds of the back, and low down on the sides of the abdomen, where I could not positively determine whether or not the peritoneal cavity had been penetrated. In other words, where we are in doubt as to the penetration use it, and if we get affirmative results, operate. I think the test is more appropriate to stab wounds, for there we are often very much in doubt as to whether or not the intestines are wounded. When we are so uncertain we should use the gas test; if it give negative results we need not operate, especially as we know that many penetrating stab wounds do not wound the intestines, whereas it is quite the exception—in fact a *very rare* occurrence for a penetrating shot wound to fail to do so.

So I conclude that the fact that a shot wound of the abdomen is penetrating, justifies laparotomy, for, unless the ball be a spent one (a very unlikely occurrence), we can be almost certain that there is serious injury to the viscera. This is a rule to which the exceptions are too few to have any weight.

The gas test then in this class of cases is unnecessary. In penetrating incised wounds, however, the character of the injury is such that the viscera may, and in fact often do, escape.

I believe that this question should be thoroughly discussed, and the truth evolved, not only for the good of our patient, but also for the medico-legal aspect of the case. Self-protection demands that the status of the test be definitely settled. I have not been able to find that any one has controverted Dr. Senn's claim that "rectal insufflation of hydrogen gas is an infallible test in the diagnosis of visceral injury of the gastrointestinal canal in penetrating wounds of the abdomen." My experience will not allow me to subscribe to the statement.

I propound the query "Is the question settled? and answer in the negative, believing it to be still *sub judice*. What say you after thoroughly weighing the facts in the above cases?"

## THE CLINIC.

### THE CLINICAL HISTORY OF A CASE OF CYSTITIS FOLLOWING TUBERCULAR KIDNEY, THE CHIEF SYMPTOM OF WHICH WAS CONTRACT- ED BLADDER; TREATED BY HOT WATER DI- LATATION.

BY I. S. STONE, M.D.,

OF LINCOLN, VA.

MEMBER AMERICAN MEDICAL ASSOCIATION, VIRGINIA MEDICAL SOCIETY AND STATE BOARD OF MEDICAL EXAMINERS; SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION; FELLOW OF THE BRITISH GYNECOLOGICAL SOCIETY, ETC.

Miss M., white, æt. 22 years, came under my care in April, 1885. She had for two years had cystitis, for which she had been treated in Washington, D. C. She was somewhat anæmic, although but slightly reduced in flesh. Her family history was exceptionally free from suspicion of tubercular disease, although her father had recently died of supposed carcinoma of the liver and stomach. The patient complained of pain extending along the ureter to the bladder from the right kidney. The pain was not constant, but was increased by pressure over the kidney or by severe exercise, as in riding or jumping, etc. The urine had sp. gr. 1020, reaction neutral, vol. 24 ozs. per diem; was heavily charged with pus to nearly one-third of its vol. Microscopical examination revealed abundant epithelium apparently from the bladder, besides pus corpuscles and abundant amorphous urates. No casts, very slight amount of albumen.

The usual treatment for cystitis gave so little relief that I sought for the cause in the urethra

and found two small papillomata, the removal of which gave some relief. She was passing urine every hour or two and was obliged to continue this through the night, causing loss of sleep and consequently loss of strength. The patient, in September, 1886, passed from my care and entered Columbia Hospital for Women, D. C., where she steadily grew worse and was discharged as incurable in December, after nearly two months' residence therein.

I was again called to see the patient and found her quite wretched and anxious to end her miserable existence. There was constant dribbling of urine, great pain in region of the bladder, extending to both kidneys, although worse on the right side. Her temperature was 102°–103°, pulse 110 to 120, attended by rigors and other septic symptoms. Her kidneys were not supposed to have to do with her condition; no tumor or other disease having been discovered by those recently in charge of her. Again hoping to benefit the patient by wise counsel, and to satisfy the demands of urgent friends in Philadelphia, she was taken to Jefferson Medical College Hospital and placed under the care of Dr. S. W. Gross, January 15, 1887. His diagnosis was "contracted bladder from cystitis with some pyelitis," which latter he thought needed no special treatment. Accordingly he prescribed hot water irrigation of the bladder, dilatation of the urethra, and argent nitr. sol., xx ad ʒj every five days. During the seven weeks' residence of the patient at the hospital, her bladder increased its capacity for urine from zero to ʒij. The general condition of the patient had greatly improved, and she was greatly encouraged with the prospect of recovery. Dr. Gross failed to detect any tumor or other disease of the kidney—save the pyelitis—and doubted the expediency of any surgical examination.

The patient was again brought under my care in March, 1887, and the treatment instituted by Dr. Gross continued. By increased pressure the bladder reached a capacity of 8 ozs. forced distension, with hot water. At this point, Dr. Gross suggested the stretching cease, but it soon became apparent that contraction would again take place, and the stretching was continued until a capacity of 19 ozs. was reached. This treatment was continued for many weeks and gave the patient great relief from the bladder symptoms. She could retain her urine for eight hours, although generally was called up twice during the night. The quantity of pus in the urine constantly diminished until about  $\frac{1}{5}$  by volume remained. Sulphate of morphia gr.  $\frac{1}{4}$  with sulph. atropia gr.  $\frac{1}{100}$ , hypodermatically, were always required to afford relief from pain during the distension. The anodyne was given only once in five days and a gain of from ʒj to ʒj secured at each sitting. This increase in capacity with morphia was sustained by daily irrigation and distension by means of hot

water, temperature  $115^{\circ}$  to  $125^{\circ}$  F., until the time would again arrive for the administration of morphia and renewed distension. Hydrochlorate of cocaine was useless in mitigating pain, both from the distension, and that from the silver solution (strong solutions of cocaine, 10 and 20 per cent., were used).

The galvanic current was used daily for six weeks of this period of treatment, but an estimate of its value could not be made, owing to the continuation of other treatment. A ball syringe was used to inject the bladder through a No. 12 soft catheter. Various means were tried to estimate the force required to secure an increased capacity, but all failed; moreover, the syringe gave entire satisfaction. The amount of pain produced by distension with hot water always proved a safe guide, and no bad symptoms followed this treatment, save slight hæmorrhage which invariably ceased when the bladder was allowed to contract. This hæmorrhage always resulted from the distension if any important gain was made in capacity. It would appear that the bladder was contracted in folds which bled when separated. This bleeding ceased when the bladder was fully opened up to 18 or 19 ozs. Iodoform in sterilized muc. acaciæ was used with great benefit, so far as could be estimated by the statement of the patient after the treatment by distension ceased. The iodoform mixture was thrown in the bladder with a syringe on alternate days, and the bladder would retain some portion of this until the next injection.

This case furnishes additional evidence of the amount of speculative knowledge of renal diseases at the present time. Although the pain was not characteristic of either calculus or malignant disease of the kidney, we know that in cases of renal calculus the pain varies greatly in character and intensity. I am fully convinced that all such cases as the one being described should have a surgical exploration made, and would have resorted to it earlier in this one but for the advice of counsel. I was confident that I had discovered a tumor of the right kidney a year before this, but as it did not continue to develop, concluded that it was a temporary distension of the kidney from an obstructed ureter.

The microscope also failed to discover positive renal disease, as shown by Dr. Brown's examination of the sediment August 7, 1887 (Microscopic Laboratory, Detroit, Mich.): "The sediment is composed entirely of urates, pus and epithelium. The kidneys are apparently not at fault."

During the first half of the succeeding year I was abroad and unable to continue the treatment of the case, and she accordingly remained with the nurse who had previously had charge of her, and who continued the dilatations from time to time. On my return she was again brought under my care and I found her retrograding. There was some loss of flesh, and a decided bronzing of the

skin. In September, 1888, during the Congress of Physicians and Surgeons in Washington, I had my friend Dr. Edwin Ricketts, of Cincinnati, see the patient, who fully agreed with me as to the necessity for surgical treatment of the kidney. Accordingly, in November, 1888, I made the usual lumbar oblique incision, and on reaching the kidney found it very hard and firmly adherent to its capsule, so as to render an examination of its pelvis very difficult. A fine needle was thrust in every direction through the mass without finding a stone. The nature of the disease appearing to be malignant, and the adhesions so strong, the wound was closed for prudential reasons. She soon recovered from this examination, and returned to her home with poor prospect for life or health. Intestinal complications occurred in three months and the patient died of inanition in March, four months after the exploratory operation.

Autopsy, twelve hours after death, disclosed healthy left kidney double its normal size. Bowels distended by flatus. Right kidney also double the normal size, densely adherent to everything, including liver, intestines and spinal column, so that a reckless dissection was necessary to obtain a portion of the growth for examination. The remains of the pelvis consisted of a collapsed sac lined with pyogenic membrane, and containing some pus, which could be forced down the remains of the corresponding ureter to the bladder. No cheesy particles could be found in the remains of the kidney, and the appearance strongly indicated sarcoma.

The bladder was similar to those usually found following chronic cystitis, the walls somewhat thickened, but free from any other appearance of disease.

I sent a portion of the growth to my friend Dr. Kemp, of the Hoagland Laboratory, Brooklyn, for examination, whose opinion was that the specimen was indicative of tubercle.

I had frequently examined the urine for tubercle bacilli without result, neither was there cough or other evidences of tubercle elsewhere. My experience in dealing with these cases of chronic cystitis goes to show an invariable causation outside of the bladder. Exclusive of toxicant causes such as the administration of such irritants as cantharides, etc., there appears to be no such disease as acute idiopathic cystitis. Cystitis is therefore remediable so far as the cause is removable. I am quite well satisfied in this opinion after consulting convenient authorities such as Emmet, Thomas, Agnew, W. H. Baker (Vol. ii, Am. Syst. Gynecology), Goodell (new edition), Reginald Harrison ("Surg. Disorders of the Urinary Organs," third edition), etc., also Morris and W. H. Dickinson, London.

It is plainly to be seen that the later writers are acting upon this theory. The length of this report prevents a greater discussion of the sub-

ject, save to say that in the three cases reported by myself<sup>1</sup> cystitis was the chief symptom, and that it was impossible to permanently cure the disease because the kidney was involved. I would also urge early resort to surgical exploration.

## MEDICAL PROGRESS.

**PTOMAINES AND LEUCOMAINES AND THEIR RELATION TO DISEASE.**—DR. JOS. LECONTE contributes to the *Pacific Medical Journal* an interesting article under this caption. He reviews briefly the germ theory of disease together with its recent modifications of interpretation and its outgrowths. With the discovery of toxic germs of diseases, it was at first believed that all the grave symptoms of a germ disease were due *directly* to the presence and multiplication of specific microbes. The first modification of this idea was, that disease in these cases was not due *directly* to the microbes, but to the accumulation in the blood of a poisonous chemical substance, a by-product of microbial multiplication, *id est* the ptomaines which may be regarded as alkaloids of albuminoid decomposition induced by the vital activity of microbes. The writer believes that we are now on the eve of another equally important modification of the original theory growing out of a recognition of the *leucomaines*—the poisonous products of albuminoid decomposition induced by *cell life*. The *leucomaines*, although formed by normal physiological processes, are highly poisonous, and inimical to health unless speedily eliminated by appropriate organs. If now there should be a failure to eliminate these toxic elements the result would be diseases similar to those produced by disease germs, except that they would lack the property of contagiousness because they are not due to the presence of microbes. The writer suggests that in view of this conception light may be thrown upon the etiology of some of those obscure sporadic and apparently non-contagious forms of fever which often puzzle the physician to classify such as some varieties of typhoid, malarial, typho-malarial, continued fever, and perhaps also a host of other indispositions of less severity. In the elimination of the *leucomaines*, the writer believes with Schiff, that the liver is the organ chiefly concerned. He believes further that this process is accomplished by the splitting of albuminoids (whether of food or of waste tissue) into glycogen (which is immediately converted into liver sugar and burned) and a nitrogenous incombustible residue which is eliminated by the kidneys as urea. Thus *leucomaines* (and perhaps *ptomaines*) are rendered innocuous, and at

the same time utilized as fuel. If these views should prove true we would have ample justification of the time honored practice of clearing the bowels and stimulating the action of the liver in the early stages of various diseases.

**THE RELATIONS OF TUBERCLE BACILLI TO THE CELLS.**—A. STSCHASTNY reports the results of investigation in this direction made in Dr. Hueppe's Laboratory in Wiesbaden. His material was the spleen and liver of the marmot, the liver of chickens and sparrows and the tuberculous tonsils of man. The results obtained were similar to those of Metschnikoff. He finds that the migratory cells, the blood and lymph channels eat the living and virulent tubercle bacilli; that in their migrations they deposit the bacilli, which they have taken up, in the tissues, and thus prepare the way for the development of genuine tuberculosis or tubercular infiltration. A portion of the leucocytes with their bacilli are converted into epithelioid cells and giant cells containing bacilli. The reporter believes it possible that giant cells also originate in fixed connective tissue cells. The giant cells in animals subject to tuberculosis may suffer a partial or total necrosis. The giant cells of animals not subject to tuberculosis are lasting active structures without apparent phenomena of necrosis, which, just as the physiological giant cells, strengthen the defenses of the organism as the result of a formative irritation.—*Cent. für Klin. Med.*, No. 33, 1889.

**STATISTICS OF PASTEUR'S INOCULATIONS.**—Pasteur's method of preventive inoculation against rabies has now been employed in 6,870 individuals, some of whom were severely wounded. Proof that the animal inflicting the injury was actually rabid has been furnished in 80 per cent. of the cases, either by experiment or by veterinary examination. The mortality among individuals, bitten by animals which were certainly mad, and treated by inoculation, amounts to 1 per cent., while the mortality of those who were not treated was 15 per cent. The mortality of patients with severe wounds of face and hands was formerly 80 per cent., while in Pasteur's institute it has been reduced to 4 per cent. The English committee appointed to investigate the value of Pasteur's inoculations, reports that Pasteur's method deserves to rank with Jenner's great discovery; the committee consisted of Sir Jas. Paget, Sir Jos. Lister, H. Roscoe and Victor Horsley.

It is interesting to note that so far it has been impossible to demonstrate the virus, much less to isolate it and propagate it in artificial cultures.

**SULPHUR AS AN ANTISEPTIC.**—SEMMOLA proposes sulphur as the coming antiseptic, most serviceable for use in derangements of the alimentary canal.

EARLY DIAGNOSIS BETWEEN BENIGN AND MALIGNANT NEOPLASMS OF THE LARYNX.

The editorial assertion of the *British Medical Journal*, that laryngeal neoplasms which originally show no trace of malignancy often assume a malignant character in consequence of the irritation produced by attempts at removal, will be remembered in connection with the case of the late Emperor Frederick the Third. The assertion was apparently based upon the opinion of MR. LENNOX BROWNE advanced to this effect as early as 1875, which position had been accepted as correct by SIR MORELL MACKENZIE and in part, but only in part, substantiated by DR. J. SOLIS-COHEN, inasmuch as he qualified by "occasionally" and "sometimes" in place of "often." "It occasionally occurs that papillomata become transformed into epithelial carcinoma, sometimes from mere local irritation from cough and pressure, and sometimes from irritation set up by repeated unsuccessful attempts at removal by evulsion." Later, Gottstein, Bosworth and Seiler spoke of the possibility of such transformations under traumatic influence, but without specifying intra-laryngeal operations.

The subsequent discussion in the *British Medical Journal*, resulted on the part of Mr. Browne in the substitution of the word "occasionally" for "often" as expressed in his original opinion, and in the inauguration, among all known laryngologists, by DR. FELIX SEMON, on behalf of the *Internationales Centralblatt für Laryngologie, Rhinologie, und verwandte Wissenschaften* of a

"Collective-Inquiry (*Sammelforschung*) relative to the Transformation of Benign into Malignant Neoplasms of the Larynx in consequence of Intra-Laryngeal Operations."

The final results of the "*Sammelforschung*" will be noticed *in due time*. Just now, it is evident, that to render reliable tabulations thus made special care is requisite regarding the correctness of the original diagnosis—a malignant or a mixed neoplasm, erroneously regarded early in the case as benign, must not be entered up as a transformation. Therefore, as essentially preliminary to the main question and as a subject of importance concerning the treatment of future cases, the *Centralblatt* discusses the early differentiation between benign and malignant neoplasms of the larynx.

With what exultation and pride in the advancement of medical science, as exemplified by the dexterity of the laryngologist and the precision of the microscopist, did we first learn that the German Crown Prince suffered, not from carcinoma, but from simple "pachydermia laryngis;" and with what sense akin to chagrin did it finally dawn upon the profession, that the Prince had escaped the danger and mutilation incident to laryngectomy, only to die; after all, of cancer of the larynx for which the radical operation had been originally proposed.

It now appears that superficial *papillomatous* excrescences are a common and early accompaniment to deep-seated carcinoma of the larynx; or, in other words, a *mischgeschwulst* may easily be present. Evidently, the fault in such cases will be neither in the dexterous extraction of a fragment, nor necessarily in the microscopic examination, but in the assumption that the part represents the whole, and consequently in placing undue reliance upon testimony thus secured.

The inadequate examination of mixed neoplasms has been the occasion of blunders, numerous and deplorable. Even VITCHEW confesses to such errors in connection with fibromata, and says: "Nothing is more deceptive than the fact that certain parts of a tumor may be formed completely of fibrous tissue while other parts have an entirely different structure, and unless one undertakes a thorough investigation of all parts he is liable to pronounce judgment according to the part only which he has happened to examine. This has occurred to myself and I remember especially such a case, diagnosticated as simple fibro-

ma, in which only after relapse and on reëxamination of the original specimen did I discover in it quite small spots of cancerous structure." Remarks which, of course, are equally applicable—*mutatis mutandis*—to new formations other than fibromata.

KRIEG, of Stuttgart, contributed to the *Sammlungsforschung*, as a case of transformation from a papilloma, one which he subsequently determined, by examination of additional sections from the original fragment, to be a mixed neoplasm: "In the oldest part there is pronounced pachydermia, *i. e.*, marked proliferation of the epithelial coating with inter-overgrowth (*Hineinwachsen*) of vascular small-cell infiltrated connective tissue papillæ. The connective tissue, beneath the thickened epithelial layer, is thickly beset with epithelial nests situated in the alveoli of the connective tissue. There is present, therefore, at the same time pachydermia and carcinoma."

In a case of known primary carcinomatous infiltration of the right half of the larynx which was accompanied secondarily by superficial papillomatous excrescences, fragments which were twice extracted and microscopically examined exhibited only the structure of papillary fibroma. And to cite still another case from the many, in the *Semonische Fall* the first pieces were microscopically those of a papilloma, while fragments removed only five days later gave unmistakable evidences of epithelioma.

Now we have no desire to dethrone our little God—the microscope, but wish merely to limit his power to his own legitimate field of action. These limitations cannot be better formulated than in the concluding words of the author of the *Sammlungsforschung*:

"The microscopical examination of fragments removed by intra-laryngeal methods in cases of doubtful laryngeal neoplasms, is a valuable but not infallible aid to clinical diagnosis. It should be used in all cases in which it is possible. This, however, is not always the case, as *e. g.* in submucous infiltrating carcinoma, an intra-laryngeal extraction of fragments cannot always be made. Has such extraction been accomplished, then one should never forget; 1, that the examination need not necessarily yield results characteristic of any particular form of tumor; 2, that, even when the examination presents apparently characteristic results, the possibility of a mixed neoplasm should be remembered; particularly so in cases in which the new formation is *clinically* suspicious while the microscope furnishes apparent evidence of its innocence. . . . The microscopist can give an opinion con-

cerning only the fragment submitted to him, not of the disease itself, unless he discovers in this fragment *positive* indications of malignancy. The examination must not be limited to a single section, but should embrace, in fine sections, the entire fragment submitted, unless the diagnosis of malignancy is with certainty sooner determined. If necessary, the careful removal and microscopic examination of fragments should be several times repeated, unless in the meantime clinical symptoms, which with our present knowledge of symptomatology are irreconcilable with benignity, establish with certainty the malignant character of the neoplasm. In such cases an otherwise indicated radical operation should not be delayed for microscopic confirmation of the diagnosis."

What, then, are the clinical symptoms which will aid so substantially in the diagnosis of certain cases? These have not yet received the detailed consideration which the gravity of the subject demands, but the *Sammlungsforschung* contains data which materially enrich our literature.

The laryngoscopic aspect of a commencing malignant laryngeal neoplasm is frequently that of a broad-based, semi-globular, or oblong wart. It may be situated at any point but is the more suspicious when, in an elderly individual, it is found upon the posterior third of the vocal cord. The color of this wart varies from white to reddish-gray. The surface, in exceptional cases, may be quite smooth, lending to the tumor of reddish hue the appearance of a fibroma. More frequently it is finely granulated like an ordinary skin-wart, or again, finely branched and villiform so that it is difficult to distinguish from a papilloma.

If benign, the wart would be wholly superficial, but being malignant it is accompanied by a *deep-seated infiltration* which though not itself apparent, yet occasions a relatively greater degree of hoarseness or aphonia, of circumscribed congestion, and later, of impairment of mobility of the vocal cord—the latter symptom being of supreme importance in the differential diagnosis. These, together with an age of over 50 years, the situation of the growth on the posterior third of the vocal cord, and the exclusion of syphilis, tuberculosis, and lupus, render a diagnosis of malignant neoplasm in the early stage, almost a certainty.

TENTH INTERNATIONAL MEDICAL CONGRESS.  
—The German Imperial Ministry of the Interior has made a grant of 80,000 marks—\$20,000—towards the expenses of the International Medical Congress, to be held in Berlin in 1890.

## A PHYSICIAN'S RESPONSIBILITY IN MEDICATION.

The present area of medical advance is characterized not only by improvements in surgical appliances, but by numberless additions to the armamentarium of the physician. In our eagerness to try the new, it would seem that some of the cardinal points in drug administration are lost sight of, or at least neglected. From a summary made from many thousands of prescriptions, it would seem that physicians generally pay close attention to dosage, and to physiological action of medicaments in the abstract, but give entirely too little attention to the factors which influence the therapeutic physiological action of drug in a given case, namely, the fugaciousness of action, the term of maximum intensity, the rapidity of absorption and elimination, and the fact that drugs act very differently in varying doses.

It has become a routine practice to give quinine in sthenic fevers, three or four grains at a dose three or four times a day, even in the early stages of fever. Quinine has but little influence in lowering the temperature when the curve is upwards. It is only when the wave has reached its height and is turning, that the drug gives a decided answer and carries the ebb far below the point it would have reached unaided. Again quinine inhibits, in some degree, the rise of temperature if a maximum effect of the drug can be obtained before the commencement of said rise. Such being the case, given the temperature record of a patient, it can be seen at a glance when to apply the remedy so as to obtain the greatest effect with the smallest quantity of drug. No general will spread his troop over a wide territory in straggling line, but endeavor, Napoleon fashion, to mass his men and throw their weight upon the weak point. We have not absolute control of disease, but lead our patient's vital forces to battle with it. Our drugs are auxiliaries. In all forms there is usually a morning remission of temperature. The time to give quinine is after the maximum wane at midnight, and before the morning rise. In this way, 10 grains of the drug will accomplish as much as one-third more of the drug given in divided doses through the day.

Bromide of potash is exceedingly slow in its action, attaining a maximum in six hours, and not being all eliminated in twenty-four to thirty-

six hours. Now suppose a patient is taking 20 grains three times a day. By the time the first dose is in full action, a second is ingested, and again a third before the previous doses have been eliminated. Therefore an epileptic taking the above dose continuously has his vaso-motor centres laboring under the impress of not 20-grain doses, but two or three times the quantity.

In contrast, we have nitroglycerin, one of the most fugacious of all the remedies used for continuous action. It attains its maximum in three to ten minutes, and is all eliminated in from thirty to forty minutes. In painful nerve affections, in local congestions and headaches, and in spasm, to obtain a rational effect from it, we must give it not two or three times a day, but almost every hour.

Chloral begins its action fifteen minutes after ingestion, and is mainly eliminated in from two to four hours. When it is desirable to maintain a sedative action over any extended period, either the dose must be repeated or some drug given in combination whose effect is more lasting.

There are many drugs that it would seem best to use in full dose at commencement, and to administer from time to time such increments as will make up the gradual loss by excretion and thus keep the patient under a more or less constant impression of the drug for hours at a time. This, it would seem, is particularly true of opium preparations.

Illustrations might readily be multiplied, but our object is not so much to illustrate as to call attention to the fact, that the smallest part of a physician's responsibility in medication is the abstract dosage—that the question before him is not how much of a drug is needed for a therapeutic response, but how much is needed in the particular case before him to meet all its requirements, and how should it be administered.

## THE AMERICAN ACADEMY OF MEDICINE.

As announced elsewhere in this issue of *THE JOURNAL*, the next annual meeting of the Academy will be held in this city during this month. The aim of the Academy deserves to be better known to the profession. It recognizes the fact that one of the principal objects of the organization of the American Medical Association was to aid in elevating the medical profession of the

United States by every practicable means, and thus securing better care for the public health; and the further fact that the investigations and reports of its committees, especially those on the education—preliminary and medical—of medical men, showed that it had done much to secure the honorable standing of the medical profession in the United States at the close of the first century of American independence, as shown in the general addresses delivered at the Centennial International Medical Congress in 1876. With a desire to supplement the work, so well begun by the American Medical Association, the Academy was organized during that congress with the design of securing the coöperation of those members of the medical profession who themselves had had the advantages of a liberal course of study before entering upon their medical studies. Believing that the advantages which result from the mental discipline gained by pursuing a classical or scientific course of study enables the medical student to prosecute his medical studies more profitably, it encourages the most liberal preparatory training, and advocates ample provision for theoretical and practical instruction by medical colleges. By concentrating its efforts mainly in the direction of securing frequent conference as to the requirements of the age, and the best methods of fitting young men for the study of medicine and the most profitable manner of pursuing their professional studies, it believes that its existence and its efforts serve a useful and an honorable purpose. It is at present engaged upon an important investigation as to the proportion of physicians now in active practice in the United States who have had the benefit of such preliminary training as it advocates. It invites the coöperation of all physicians who not only desire, but who will aid in securing for those entering the medical profession, and who are to fill our places in it in the future, the best equipment for it.

#### EDITORIAL NOTES.

##### HOME.

**NEW BUILDING FOR THE PHILADELPHIA POLYCLINIC.**—The contract for the erection of the new college, hospital, and dispensary building of the Philadelphia Polyclinic and College for Graduates in Medicine, was awarded October 5.

The new structure will rest on a lot 96 feet by

143 feet, about three blocks from the present temporary quarters, and will be of brick, sandstone, and terra-cotta. It will be four stories in height, and will occupy at present only one-half of the lot.

The important features of the building will be the incorporation of the most modern accepted plans in hospital construction.

The system of heating will be by indirect radiation, and the ventilation that of sub-stratum suction. All corners in the building will be rounded to avoid the accumulation of dust. The water-closets and bath-rooms will be in a separate building easily accessible from all parts of the building. The kitchen and laundry will be at the top, separated from the lower floors by an artificial stone floor. The clinic rooms will be on the first floor in direct communication with a spacious waiting-room.

The corner-stone was laid with impressive masonic ceremonies on the 2d inst.

**DR. CARL KOELER**, the discoverer of cocaine anæsthesia, has been made instructor in Ophthalmology at the New York Polyclinic.

**THE AMERICAN ACADEMY OF MEDICINE** which meets in Chicago on November 13 and 14, will hold its sessions at the Leland Hotel. Dr. Lester Curtis is Chairman of the Committee of Arrangements. Dr. S. J. Jones is Chairman of the Committee on new members, to whom applications for fellowship in the Academy may be addressed. A cordial invitation is extended by the Academy to physicians to attend its meeting, and especially to those who are interested in a higher standard of qualification for the medical profession, beginning with the preliminary education of students.

##### FOREIGN.

**DR. PHILIPPE RICORD** died in Paris, October 21. He was the world renowned syphilographer, and was very often spoken of as the great American physician of Paris. He was born in Baltimore, December 10, 1800. His father was a native of France, and young Ricord went to Paris in 1820, and took his medical degree in 1826. After a few years he settled for life in Paris, and went to the front rank in surgery. He was Court-Surgeon under the third Napoleon, and was the recipient of numerous decorations. Notwithstanding his advanced years, he was until quite recently a prominent character in Parisian medical society.

## TOPICS OF THE WEEK.

### THE UNITED STATES CENSUS IN ITS RELATIONS TO SANITARIANS.

From a paper presented by DR. JOHN S. BILLINGS at the annual meeting of the American Public Health Association held in Brooklyn October 25, we make the following extract:

Theoretically we all agree that vital statistics are the foundation of public medicine; but practically, the majority of sanitarians and physicians think that they are not essential to the work of a health officer or Board of Health, although they may be desirable. That the main objects in sanitary work are to see that the water supply is pure, that garbage and excreta are promptly removed or destroyed, that no filth is allowed to accumulate in the vicinity of habitations, that contagious diseases be controlled by isolation and disinfection, and that plenty of fresh air be provided in schools, churches, etc., and that all this can and should be done whether death-rates are known or not. Occasionally it is possible to get up a cholera, or yellow fever, or small-pox or typhoid fever scare, and to thus get a little money for sewerage or for street and alley cleaning; but these spasmodic reforms do not last long, and in most cases do not amount to much. You have got to produce constant, undeniable evidence that the work is needed and is useful; evidence that will convince the press and the majority of the community, and this evidence must be mainly death-rates, to which should be added all the sick-rates that can be obtained.

To give these death-rates you must have a complete registration of deaths and a corresponding enumeration of the population, and you ought to have a complete registration of births.

Before this Association meets again the eleventh United States census will be taken, and its methods, its completeness, and the mode in which its results will be tabulated and published, are of great interest and importance to all who are interested in sanitary science or in public health work in this country.

One of the most important questions, then, to be settled before the census is taken, is: What shall be the boundaries of the special districts of the city for which a separate statement of the population is desired?

For about a dozen of our large cities it is proposed to make a systematic division of the area into sanitary districts having special relations to altitude, character of habitation or of population, etc., and to have special death-rates calculated for each of these districts. This is being done in conference with the health authorities of these cities, and it is hoped that in this way some very interesting data will be obtained which will serve as a foundation for sanitary work in the future. Such districting has been arranged for Boston, New York, Brooklyn, Washington, New Orleans and Louisville, and the work is in progress for other cities. In investigating the details of the records of deaths kept in different cities I have noted deficiencies in a few of them to which I wish to call the attention of all who have to do with the registra-

tion of vital statistics. First, all deaths occurring in hospitals should be charged to the ward or district of the city from which the patient was taken to hospital, where this can be ascertained. Otherwise the death-rate in the ward in which the hospital is located will be too high, and in the other districts it will be too low.

Second, the birthplace of the parents of the decedent should be reported. We want to know the race of the decedent—whether he was German, Italian, Irish or American, and to give merely his own birthplace is not sufficient.

Third. It is very desirable that in all cases of deaths of colored persons it should be stated whether the decedent was black or of mixed blood, such as mulatto or quadroon.

One of the most important questions in the vital and social statistics of this country relates to the fertility, longevity and liability to certain diseases of those partly of negro and partly of white blood, and the only way to obtain data on this subject is through the registration of vital statistics.

Under the provisions of the law providing for the census, the living colored population is to be enumerated with distinction as to whether such person is black, mulatto, quadroon or octoroon, and we need the same distinctions for all persons dying during the census year, to enable us to calculate comparative death-rates. Wherever there is a fairly accurate registration of deaths, which now exists in several States, and in over 100 cities, the next census will afford the means of calculating the death-rates, with distinctions of color, sex and age which will furnish important indications for sanitary work.

I have no authority to make specific promises, but I believe that the reports of the next census, in which the members of this Association are specially interested, will be published as soon as it is possible to compile them, and will be distributed to those sanitarians and physicians who need them in their work and who make timely request for them; and thus believing, I do not hesitate to ask the cordial coöperation of all members of this Association to make the data upon which these reports are founded as full and accurate as possible.

### CHANGES IN THE GANGLION CELLS AFTER STIMULATION.

The theory has for a long time been held that the change in activity in the central nervous system, that is, the performance of its function by any nerve centre composed of ganglion cells, was accompanied by some physical or chemical change in the cells. This theory has at last received demonstrative evidence in its favor from certain recent investigations. Korybutt-Daszkievicz<sup>1</sup> has attempted to solve the question whether the activity of the central nervous system is accompanied by changes recognizable with the microscope. His experiments were conducted on two frogs of the same weight and sex. One was kept as a control, in the other the eighth nerve was stimulated by induction shocks for an hour. The cords of both were hardened and stained by Gaule's method with hæmatoxylin, nigrosin, eosin, and safranin.

<sup>1</sup> Archiv. f. mik. Anat., 1886, p. 51

The nuclei of the ganglion cells were the point of chief interest. These stain red and blue, but he finds that 3.31 to 3.66 times more nuclei stain red in the stimulated frog than in the unstimulated frog. Hodge, who has investigated the same subject, questions the accuracy of this method, thinking that the red nuclei are more superficial than the blue, and that the thinner the section the greater the number of red nuclei. Hodge's method was to stimulate one or more nerves on one side of the body, and then remove the corresponding spinal ganglia on both sides, keeping them together all the time in the hardening and staining fluids, and making simultaneous sections. The treatment is thus absolutely identical, the only difference being that one ganglion has had its nerve stimulated while the other has not. He finds that the stimulated ganglion shows distinct differences; the nuclei in its cells are smaller, the outlines are jagged and irregular instead of round, and there is a loss of open reticular appearance with darker stain. The cell protoplasm shows a slight shrinkage in size, it has a lessened power to stain or to reduce osmic acid, and it becomes finally granular and reticulated. The cell capsule also shows a decrease in the size of its nuclei. These investigations are practically the first undertaken upon this subject, and their importance as confirming the theory of nerve action is great. They indicate, moreover, the importance of applying similar methods in the investigation of so called functional diseases of the nervous system, for they seem likely to render the old distinction between functional and organic disease of no value.—Philip Coombs Knapp, in *Boston Medical and Surgical Journal*.

#### STEAMSHIP SANITATION.

Among the subjects to be discussed at the meeting of the American Public Health Association at Brooklyn this month (October) is "Steamship Sanitation." The matter is one of considerable importance to the Eastern States, and through them to the whole Union. Owing to the supineness of the Board of Trade and the shortsighted selfishness of the steamship owners, there is a continual danger that whole shipfuls of passengers may be landed at New York, Boston, or any other Eastern port, bearing with them the germs of infection contracted during the Atlantic voyage. The inspection of emigrants at British ports, though carried out, we believe, as a rule, by the medical officers with the most conscientious care which the circumstances permit, is little better than a farce. The emigrants are gathered upon the wharf and at a signal admitted on to a narrow gangway, along which they struggle with their bedding and all the small impedimenta for the voyage. As they issue from the gangway they are hastily inspected, and any case presenting obvious or suspicious symptoms is made to stand aside for more careful examination. Even this rough inspection is better than nothing, and a practised eye will no doubt weed out most of the dangerous cases. If the surgeon of the ship could always ensure the isolation of the suspected cases, a very great step would be taken towards the attainment of the desired end. Unfortunately this is by no means always the case; if the

ship is full, the space set apart for the hospital is very apt to be used by the agents for berthing ordinary passengers. If the surgeon protests, he is snubbed, and if he records the fact in his report, which ought, according to regulations, to be forwarded to the Board of Trade when the vessel returns, he is very likely to have the document returned to him by the agents with the intimation that the matter is one which does not come within his province. It is within the powers of the Board of Trade to compel the steamship companies to obey the law as to the reservation of the ships' hospitals for the use of the sick alone; and it is not easy to understand why frequent and repeated breaches of the law are winked at by the officials.—*The British Medical Journal*.

#### THE ESSENTIALS OF SUCCESS.

SIR ANDREW CLARK, who has achieved a professional reputation which is world-wide, had occasion, in a recent address, to give his views of what is required to make a man a successful physician. In that address he uses the following language:

Firstly, I believe that every man's success is within himself, and must come out of himself. No true, abiding and just success can come to any man in any other way. Secondly, a man must be seriously in earnest. He must act with singleness of heart and purpose; he must do with all his might and with all his concentration of thought the one thing at the one time which he is called upon to do. And if some of my young friends should say here, "I cannot do that—I cannot love work," then I answer that there is a certain remedy, and it is work. Work in spite of yourself, and make the habit of work, and when the habit of work is formed it will be transfigured into the love of work; and at last you will not only abhor idleness, but you will have no happiness out of the work which then you are constrained from love to do. Thirdly, the man must be charitable, not censorious—self-effacing, not self-seeking; and he must try at once to think and to do the best for his rivals and antagonists that can be done. Fourthly, the man must believe that labor is life, that successful labor is life and gladness, and that successful labor, with high aims and just objects, will bring to him the fullest, truest and happiest life that can be lived upon the earth.

#### THE LATE DR. JOULE.

DR. JAMES PRESCOTT JOULE, who died at Sale on October 9th, in the 71st year of his age, was one of the most distinguished men of science which this country has ever produced, and is entitled to be reckoned one of the greatest of original workers in pure science. His great achievement was his determination of the mechanical equivalent of heat. The consequences flowing from the working out of this problem, which was achieved by Dr. Joule with the most consummate skill and admirable completeness, are to be noted in almost every department of science; upon his demonstrations the whole theory of the correlation of forces is mainly based. The most important practical applications have been in the mechanical arts, but even physiology is his debtor.

## PRACTICAL NOTES.

## THE DIGESTIBILITY OF BOILED MILK.

It is now very regularly recognized, both by medical men and by the more highly educated section of the community, that it is a wise precaution to boil both water and milk before using them as beverages, and the practice is becoming very common. The growth of pathogenic organisms in these fluids, especially in milk, is often very rapid, and thus diseases may be transmitted from one place to another. The temperature of boiling water puts an end to the life of the microbes, and also to the danger of infection. Another reason why boiled milk is so much used, especially in infant feeding, is that it is supposed to be more easily digestible than fresh milk. If, however, we can draw correct deductions from dogs to babies, it would now appear that this belief in the superior digestibility of boiled milk is founded on error. Dr. Randnitz, of Prague, has recently published, in Hoppe-Seyler's *Zeitschrift für physiologische Chemie*, certain very striking experiments on this subject. He admit, what anyone may confirm for himself, that milk that has been boiled does not, on cooling and the subsequent addition of rennet, form a large coherent clot, as does fresh milk, but a flocculent precipitate of casein is produced instead. He shows, however, by analysis of the milk itself and of the urine and feces, that much less nitrogenous material is absorbed from milk that has been boiled than from the same milk when fresh. The digestibility of fat is apparently unaltered by boiling; the following figures, however, illustrate the fact just alluded to as to the difference of digestibility of the proteid materials: In three days 15.6 grams of nitrogen were given in the form of fresh milk; of this quantity 13.3 per cent. was found in the feces; the nitrogen of the urine accounted for 77.3 per cent., so that 9.4 per cent. was retained in store by the growing animal. The animal was next fed on boiled milk, and 10.4 grams of nitrogen were given in that form for two days; 18.6 per cent. of this was found in the feces, 75.7 in the urine, so that only 5.7 per cent. was assimilated. The belief in the superior digestibility of boiled milk is, however, so widespread, that we should like to hear of the confirmation of the above remarkable results before we recommend mothers to leave off what is, from other points of view, the very praiseworthy custom of boiling the milk they give to their children.—*British Medical Journal*.

## TREATMENT OF DIABETES BY ANTIPYRIN.

DR. JOSEPH S. CARREAU, of New York (*Med. Record*), cites three cases of this disease success-

fully combated by this remedy. He also states the fact that Dujardin-Beaumetz, at a meeting of the Académie de Médecine, April, 1888, praised the happy effects of antipyrin in certain cases of diabetes, especially when the two symptoms, polyuria and nervous irritation, predominated. Henri Huchard, at the Société de Thérapentique, February, 1888, said that he employed antipyrin in a case of symptomatic polyuria resulting from meningo-myelitis, with good effects. He gave from 4 to 6 grams daily, and the quantity of urine was brought down from thirty-six litres to four. He also reported a case of diabetes, where he noticed, in a few days, the sugar diminish from 735 to 271 grams a day under the use of antipyrin—two to six grams daily. He also said that the prolonged administration of antipyrin, in his own experience, has never been followed by albuminuria.

M. Panas reported two cases to the Académie de Médecine, April, 1889, where great relief followed the administration of antipyrin. A man aged 38, passing 49 grams of sugar in twenty-four hours, by taking 2 or 3 grams daily during six days, had all traces of sugar in his urine removed. A woman, aged 73, by taking 3 grams daily for a few days, also received similar benefit.—*Canada Lancet*.

## SALICYLIC ACID IN TYPHOID FEVER.

DR. SCHAKOVSKI (*Thera. Monatsh.*) claims great success from the use of salicylic acid in malignant scarlatina. He has used it in 125 cases. The mortality is but 3½ per cent. The following formula was used:

R Acidi salicylici . . . . . 1 part.  
Aque destillatæ . . . . . 75 parts.  
Syr. aurantii cort . . . . . 30 parts.

M. Sig. Give a teaspoonful every hour during the day, and every two hours during the night.

The temperature falls very rapidly after taking this mixture, so that in certain cases, inside of forty-eight hours, the temperature has fallen from 105.8° F. to 100.4° F. All trace of fever vanishes by the tenth day. Nevertheless the author advises the continuance of the remedy for some time, in decreasing doses, to prevent a relapse. All serious complications, such as uræmia, anasarca and diphtheria, are avoided through this treatment. The treatment is ineffectual only when employed too late (after the fourth day of the illness), or where grave complications already exist.—*Medical Standard*.

## A REMEDY FOR NEURALGIA WITHOUT MORPHINE.

R Antipyrin . . . . . 3 iij.  
Ex. cannabis Ind. . . . .  
Ex. aconite . . . . . 55 gr. vss.  
Caffein . . . . . 5 ss.  
Hyoscinæ hydrobrom. . . . . gr. T.  
Divide into 30 capsules.

## SOCIETY PROCEEDINGS.

### The American Public Health Association.

The American Public Health Association met this year at Brooklyn, N. Y., for its seventeenth annual session. It occupied part of four days, from October 22 to 25. In the number of its attendance and the quality of the scientific results the verdict, on the part of its *habitués*, has been that the meeting was a success. Not much time was allowed to run to waste on outside entertainments: the unwritten law of the Association being distinctly in favor of giving the minimum of time to excursions, collations and the like. Three diversions were permitted at Brooklyn.

The first was the exhibition of sanitary apparatus, food materials and the customary range of inventions promotive of good health, that finds place in this kind of exhibition. This is the first exposition of the sort that has been attempted at any annual session of the Association. It was a modest show, tentative in extent, but sufficiently attractive to make it probable that it will be tried more fully at future meetings, when the local committees shall see fit to give their time to it. The present report is that the exhibition has been self-sustaining; an income having been derived from the rental of floor space to the exhibitors.

The second diversion was a public meeting held at the Academy of Music, on the evening of the first day, in order to extend the freedom of the city to the visitors. At this meeting, which the citizens and especially the medical profession attended *en masse*, addresses of welcome were delivered by the Mayor of the city, Mr. Chapin, Dr. Alexander Hutchins, for the profession, the Rev. Dr. R. S. Storrs and ex-Mayor Seth Low, who has just been elected to the Presidency of Columbia College, in New York City. These are four speakers who, in their respective fields, are held in highest esteem in the community. The address of Dr. Hutchins was, in a marked manner, approved and enjoyed by the medical members present.

The third diversion was an excursion, by steamer, on the afternoon of the second day, to the Quarantine Station on the Lower Bay of New York Harbor. The original plan of this excursion included a visit to the islands in the East River, on which are located the charitable institutions of New York City, but lack of time prevented the carrying out of that part of the programme; the blustering weather, also, was rather adverse to a prolonged sail after visiting the objects of interest in the harbor below. Two hundred and twenty delegates and their friends took the excursion. A collation, given by the citizens of Brooklyn, was served during the sail. The

visit to the quarantine islands was upon the cordial invitation of Dr. William M. Smith, for many years the Health Officer of the Port of New York. Dr. Smith sought this as a favorable opportunity of explaining the *modus operandi* of a modern, non-stringent quarantine, and of making better known to the official members of the Association some of the changes instituted by him in recent years. With the exception of the foregoing, the time of the Association was wholly given to the consideration of scientific business.

The notable papers, prepared for the convention, included one by Dr. John S. Billings, U. S. Army, who took for his subject *The Sanitary Relations of the Federal Census*; one by Dr. George M. Sternberg, also of the Army, who treated of *Yellow Fever and its Etiology*, therewith presenting microphotographic illustrations by means of the stereopticon; one by Mr. Edward Atkinson, of Boston, on *The Economics of Cooking*, made plain by the preparation and service to the audience of a hot supper, cooked in ovens invented by himself, over two oil lamps, while his lecture was in progress; one by Dr. Salmon, of the National Bureau of Animal Industry, who gave an illustrated discourse on *The Texas Cattle Plague*; also a paper by Prof. W. O. Atwater, of Washington, on *The Physiological Chemistry of the Diets of various Nations and Occupations*.

The stimulating and instructive nature of many of these addresses, as well as of others on the various problems vexing the medical officer of health, was manifest in that they called forth a volume of debate which was far in excess of the time apportioned to the discussion of papers. If a full week had been the length of session, it would have been none too long to have been occupied by the themes that were ripe for consideration in the minds of the members. The presiding officer had frequently to cut short an interesting subject by reason of the preassignment of the time to other interesting matters.

*The Presidential Address* of Dr. Hosmer A. Johnson was cordially received by the popular audience to which it was read (see JOURNAL, November 2, 1889).

*The Overshadowing of our Homes*, by Dr. Thornton Parker, of Newport, was the subject of the first paper of the first day. The contention of this paper was adverse to the large or general employment of shade trees, as exemplified in the towns of New England. Dr. Maxwell, of Florida, and others from the Southern States defended the shade tree.

*Infant Mortality* occupied the afternoon session of the first day very fully. Papers of exceptional value were presented by Dr. Jerome Walker, of Brooklyn, and Alfred White, Esq., also of Brooklyn; the latter giving the results of a large experience in the construction of improved tenement houses. Dr. George Homan, of St. Louis,

offered some suggestions regarding the compensation due to health officials.

On the second day, Dr. Billings gave an outline of the proposed studies in vital statistics to be carried out under the coming census, inclusive of new features to be introduced in regard to the sanitary districting of ten or more of the larger cities. His propositions elicited much discussion. Dr. J. N. McCormack, of Kentucky, in this connection, introduced a resolution instructing that an effort be made to establish cordial relations with Cuba and Mexico, in respect of the sanitary departments and undertakings of those countries. Later this was adopted by the Executive Committee.

Dr. Ezra M. Hunt, of New Jersey, took up the subject of *Phthisis Prevention and the Methods, indicated by the latest Researches, to be employed to that End*. The discussion of this subject was deferred until the following day, when it was opened by Dr. J. S. Billings, who inclined to limit the preventive official measures to precautions against the aerial diffusion of dried phthical sputa.

Dr. Gihon, of the U. S. Navy, introduced a resolution declaring the sentiment of the Association to be favorable to the adoption of preventive means, as to the disease in question, so far as to recommend the destruction of the tuberculous sputa.

The further discussion of the prevention of tuberculosis was taken up on the afternoon of the third day, the papers introductory thereto being presented by Dr. Edward Playter, of Canada, and Dr. P. H. Kretschmar, of Brooklyn. The latter speaker defended the doctrine of the heredity of phthisis pulmonalis and laid down the following propositions:

*First.* If there are many children in a family, those born after the sixth or after the seventh are apt to develop pulmonary consumption.

*Second.* If the children in a large family are born at short intervals, say one year, the younger ones are apt to develop pulmonary consumption.

*Third.* If the offspring of healthy parents, born under conditions named above, escape the disease, their children are apt to develop pulmonary consumption.

The discussion was animated on every point bearing on the prevention of the spread of tuberculosis, and is destined to be renewed at future meetings, many members not having had a full freedom to express their views.

Prior to the midday excursion, on the second day, remarks were made by Health Officer Smith and Dr. Raymond explanatory of the conditions and modifications of quarantine administration in the harbor of New York. The remarks of Dr. Smith dealt largely with details of construction and will, when printed, have that value that belongs to a work of reference. It transpired later that while, or about the time, these remarks were

being made, there was delivered at the morgue of the quarantine hospital the body of a yellow fever victim, a sailor who had died a few hours before on a steamer coming in from a Central American port. A few members only knew what the morgue contained.

The morning session of the third day, October 24, was chiefly given up to papers and discussions having relation to garbage disposal and the pollution of streams. The chief papers were by Drs. Martin and Kilvington, the Health Commissioners of the cities of Milwaukee and Minneapolis. According to Dr. Martin the cremation of city refuse had not proved to be the success that it promised to be in the Western cities. He said:

"Cremation as a system has had its day, and a brief one it has been.

"The present system in the city of Milwaukee is the Merz system, which, from June 11 last, has given the best of satisfaction. The quantity of garbage collected is 40 tons daily, which with that brought to the works by the commission dealers, wholesale men and grocers, brings the total up to 50 tons, which is promptly disposed of. The works are situated in the slaughter house district, and the building is a two-story frame, 62 by 110 feet. The garbage teams drive up an inclined roadway to the second story, where the garbage is thrown on the floor to be scraped into the driers, of which we have eight. The time occupied in drying the garbage varies, of course, with the quantity and amount of moisture, but is usually from eight to eleven hours."

Another practical subject, the use of sulphur as a disinfecting agent in the hands of sanitary officials, was brought to the front by a paper by Dr. Cyrus Edson, of New York City. Many health officials participated in the debate on this subject. The preponderance of opinion seemed to be in favor of the value and efficacy of sulphurous fumigation when thoroughly performed, and when the vapor of water was freely generated in the apartment containing the infected materials; also that the wetting of articles with water is not desirable, lest there be a bleaching process set up and a damage to certain fabrics by sulphurous acid gas.

On behalf of Dr. Rauch, of Chicago, the following motion was introduced and suitably referred:

WHEREAS, Asiatic cholera, leaving its usual restricted bounds, threatens to advance by the same lines that it has followed in the last four epidemics, be it

*Resolved*, That the American Public Health Association desires to call renewed attention to this fact, and to urge that quarantine authorities on the Atlantic and Pacific seaboard and boards of health throughout the country make every effort to prepare for this threatened danger.

The evening of the third day had two papers finely illustrated by stereopticon views: first, a paper on *Sanitary Disposal of the Dead*, by Rev. Charles R. Treat, of New York City; second, one

by Dr. Benjamin Lee, of Philadelphia, on *The Sanitary Reasons why Cuba should be Annexed to the United States*. The dangers from yellow fever, small-pox and leprosy, under the present Cuban Government, are such, Dr. Lee maintains, that this country may lose, in a single season, by imported infectious disease, more than the island of Cuba is worth if it were bought outright from her proprietors, at their own valuation. The illustrations of leprosy, presented by Dr. P. A. Morrow, of New York, were greatly admired; the closing one being a portrait of the late Father Damien, the leper priest of Molokai.

According to the paper of Rev. Mr. Treat the newly proposed plan of sanitary entombment will bring down the cost of corpse disposal to about \$15 for each body entombed.

The morning of the fourth day, chiefly occupied though it was by official reports and routine business, was partly given up to a discussion of *The Causes of Infant Mortality*, based upon a vigorous paper, prepared by Dr. R. O. Beard, of Minneapolis, and read by Dr. Gihon. Several health officers participated in the debate, who showed the difficulties they have to contend with on account of the vague or misleading nomenclature of the causes of death employed by many physicians. Dr. G. C. Ashmun, of Cleveland, instanced the use of the term "marasmus," by physicians of prominence, to cover nearly every case of infantile mortality, especially when the mortality must be published in institutional reports. The phrase indicates nothing that is useful for statistical or sanitary purposes, and should be put in the same category with "debility" and "heart failure."

Dr. W. M. Smith held that it should be the duty of every health officer to decline to accept certificates of death which evade, omit or vaguely state the cause of death, not less with regard to infant than adult mortality.

Growing out of this discussion, a motion was made for the appointment of a special committee, Dr. Jerome Walker, of Brooklyn, to be chairman, to consider *The Causes and Prevention of Infant Mortality*, and report, from year to year, at the discretion of the Executive Committee.

The convention closed about noon on the fourth day, up to which time the attendance continued creditably large. By some of the members it was pronounced the most satisfactory in the past history of the body.

The officers elected for the coming year are as follows: President, Dr. Henry B. Baker, of Michigan; first Vice-President, Dr. Frederick Montizambert, of Quebec; second Vice-President, Dr. Joseph H. Raymond, of Brooklyn. The Secretary, Dr. Irving A. Watson, and the Treasurer, Dr. Berrien Lindsley, were re-elected. The following elective Trustees will serve one year: Dr. H. B. Horlbeck, of Charleston, S. C.; Dr. L. T.

Salomon, of New Orleans; Dr. Wm. Bailey, of Louisville; Dr. Peter H. Bryce, of Toronto, Canada; Dr. J. F. Kennedy, of Des Moines; and Dr. Walter Wyman, of Washington, D. C. The time of holding the next meeting, not definitely fixed, will be early in November, 1890; place of meeting, Charleston, S. C.

On motion of Dr. Plunkett, of Tennessee, a special vote of thanks was tendered to Dr. J. H. Raymond, chairman of the Brooklyn local Committee of Arrangements, for his arduous and successful efforts on behalf of the convention then drawing to a close. The daily papers of Brooklyn and New York City were very cordial and appreciative, reporting the proceedings very fully and praising without stint the efforts of the members on behalf of the preservation of public health.

### Obstetrical Society of Philadelphia.

*Stated Meeting, September 5, 1889.*

(Concluded from page 647.)

DR. JOSEPH HOFFMAN reported

A SERIES OF ABDOMINAL SECTIONS, WITH  
SPECIAL REFERENCE TO COMPLICATIONS.

He said: The list of operations may be classified as follows: One strangulated ventral hernia; one appendicitis and hæmatocele; sixteen cases of ovarian and tubal disease with adhesions, inflammation, and occlusion of the tubes, with one death, the result of sepsis. Where the infection came from, for a long time puzzled me. Months after the death I learned that the patient had had a miscarriage brought on instrumentally, and the mystery was solved. In other words, I believe the tubes were septic, and gave rise to the peritonitis.

By this case I believe there is sufficient learned to warrant the practice of cauterizing the tubes after ligation and section in all doubtful cases where there is the least suspicion of infection. If this is not done, they should be thoroughly disinfected and the abdomen drenched. I have had no other death from like cause, or from peritonitis from any cause. Six cases of pyosalpinx; one occurred during pregnancy, and the operation was done to save life. The woman miscarried the fourth day after the operation, but made an excellent recovery, though her pains were very great during miscarriage, and were only controlled by the free use of morphia and atropia. All cases of pyosalpinx recovered. They are all working in comfort, save one, who has lately died of tuberculosis. This last case is strongly in support of Bernutz's view, that pus in the tubes is a forerunner of general tuberculosis.

In two cases, the gonorrhoeal origin of the

pyosalpinx is well established ; in two, the history points to post-puerperal origin ; in the remaining two, the origin is doubtful, though in one of the cases I strongly suspect a specific start.

One died of shock—never coming out of anæsthetic. She was a hard drinker.

In two cases the tumor removed was dermoid. Both were small. In one of these cases the uterus was rudimentary, though the woman had for a long time worn a pessary for a so-called displacement, introduced by a specialist in gynecology.

There is sufficient commentary here on the use and abuse of pessaries without further remark. In two cases exploratory incision was made. In both, the women recovered quickly. One of these soon after died after tapping ; from what cause, I do not know. I visited her for a day or two after tapping her, and was told that the patient was feeling so well that no further visit was necessary. In a week, or thereabouts, I learned of her death in the hands of another. The whole air of the matter was unsavory, and I am not sorry to remain in ignorance concerning it. The second exploratory incision was due to an error in diagnosis. The uterus was retroverted, a miscarriage having occurred a short time previously. There was a peculiar thickening of the right broad ligament, which immediately led to the blunder. I examined the patient on my table soon after her recovery, and had I not known that I had erred before, the condition was such that I would have done so again. Two small ovarian cysts ; both recovered. One case of omental hernia, one case of extra-uterine pregnancy. One case of operation for adhesions due to previous operation. The result has now a greater measure of success than I hoped for a short time ago.

The drainage tube was used in fourteen cases. I believe I would have had a better chance of saving one of my deaths had I used it. I have never had a death from its introduction. I have had but one fistula persisting after its use, and this now gives every sign of closing. In only one case has there been a discharge of the ligature. The patients operated upon are now all living but four. They are all able to do their work comfortably save two. One case, I believe, is reported to have had another operation. She was a most ungrateful baggage, and I trust she will tarry a long while on earth for the experience she will bring to others. I have had one case of hernia after simple section. The woman was fat, and neglected her bandage. In two cases where it existed previously to operation it still is present. I did not really operate for its cure. I have found drainage and flushing the abdomen to be of the greatest service in cleansing the abdomen of *débris*, and believe them indispensable. Free saline purgation, or when the

salts are not retained, mercurial purgation, is of the greatest benefit in severe wind-pains. These are probably more frequently the cause of pain soon after the operation than inflammation, though there is no doubt that here, also, these purges are of undoubted value. In the question of diagnosis, I find it is much easier to say there is a lesion than to map it out exactly or to define it. I have found marked trouble in cases where expert examination pronounced disease absent ; in others, where one thing seemed to be the trouble, another was found present. So far as pain is concerned, it does not always indicate the spot of the lesion. I have found one side the most diseased when it was freest from pain.

In the thirty-three operations recorded, two deaths have occurred. No patient was operated on by myself more than once. The first death occurred early in the series. In the last twenty-six cases there has been but one death. The last eighteen cases have been without death.

DR. JOSEPH PRICE reported

#### TWO OPERATIONS FOR EXTRA-UTERINE PREGNANCY.

The first case I have to report is that of a white woman, æt. 35, nursing a child of 13 months. Menses appeared on the fourth month of lactation, and remained perfectly regular at intervals of twenty-seven days ; four days duration ; were absent two periods, followed by paroxysms of pain and collapse. At this point I saw her, and operated immediately for ruptured tubal pregnancy. I found about a quart of clotted blood in the peritoneal cavity ; tubal rupture left side ; hydro-salpinx right side. Clean removal of both sides ; irrigation ; drainage ; recovery.

The second case, occurring in a pure negress, is of great interest. I am not satisfied, from the microscopical appearance, that it is a true ovarian pregnancy. Ovarian cysts are very rare in true Africans. In the blood cyst, I found something for all the world like placenta and membrane. I do not wish to put this on record as an ovarian pregnancy until I receive the report of Dr. Henry Formad, the pathologist. There also existed in this case a hydro-salpinx of the other side—both demonstrating most beautifully the causal relation of tubal disease to ectopic gestation. One point of great interest in connection with these cases that survive the rupture and go into the hands of the surgeon, is the marked difference in the character of the hæmorrhage from those that go into the hands of the coroner—and they are numerous. In the latter cases, the hæmorrhage is overwhelming, and the abdomen is found full of blood. The surgeon finds probably one-fourth the blood. Dr. Formad, the coroner's physician, tells me that in one case he found the peritoneum deluged with blood, and the little foetus sitting, or washed up on the pan-

creas. Its object was probably to try and escape a possibility of electrical treatment.

DR. J. M. BALDY reported a case of

#### FIBRO-CYSTIC TUMOR OF THE UTERUS.

Mrs. A., æt. 35 years, married, no children. Has had a lump in her abdomen for fifteen years, which remained quiescent until within the last two years, since which time it has grown rapidly. Menses have gradually become irregular and profuse; bowel and bladder symptoms have become severe; pus has appeared in the urine; abdomen is constantly swollen, and very painful; general health had begun to suffer severely. Examination showed a uterine tumor, and its removal was advised, the dangers of the operation being fully explained. Operation was eagerly accepted. The tumor was removed one week ago last Tuesday, and proved to be an extremely nodular fibroid, which had undergone cystic degeneration in part, and in other parts is quite cedematous, as can be seen by the specimen which is here before you. The mass was firmly wedged into the pelvis, and was delivered with the greatest difficulty, leaving practically no pedicle at all. The case was treated by supra-vaginal amputation, a wire nœud being first placed around the lower portion. The stump was treated by the extra-peritoneal method, as advocated by Bantock. After the tumor had been cut away, there was left a stump with a diameter of over three inches; this was gradually trimmed away until it was reduced to about an inch and a half in diameter. The operation was altogether the most trying and most difficult one of this kind I have ever performed or seen.

This case presents the opportunity for a few remarks on the method of treating the pedicle in hysterectomy, and on the use of electricity in fibroid tumor of the uterus.

There are two methods of treating the stump—the intra-peritoneal, as advocated by Martin, and the extra-peritoneal, as advocated by Bantock. All other methods devised or proposed are simply modifications of these two, and are far from being as good as the originals. A so-called half-way method proposed by Kelly last winter has so many objections for general application, that it is hardly worthy of consideration, excepting for picked cases; and these must be cases of the simplest kind, with a pedicle which can be easily dealt with. In the *New York Medical Journal*, for July, Douglas has called particular attention to the defects of this departure.

What we want are results, and in questioning different gentlemen who are experimenting with the so-called improvements in hysterectomy, I find almost universally that their losses amount to from 30 per cent. to 50 per cent. The patients who get well may do so quickly, and the operations may be very beautiful, theoretically, but

the results are murderous! Until a larger number of cases have been reported, and the results are very decidedly better, I prefer to pin my faith to one or other of the two original methods. Of these two, the results obtained by the extra-peritoneal method are, at present, very decidedly the best, and have proven eminently satisfactory in my hands. Martin, by the intra-peritoneal method, reports a series of eighty-four cases, with twenty-five deaths. Later, he has thirty cases, with three deaths; and still later, he has "another series with good results;" and last, a series with bad results." And so, after an experience of much over one hundred and twenty-five cases, he ends up with a series so bad that he does not publish it. In contrast with this stands Bantock's record, by the extra-peritoneal method, of fifty-seven cases with only twelve deaths, and his results continually getting better to the end. He now has a run of thirty or forty cases without a death. These figures speak for themselves. After all his experience, Martin ends by saying, "So I think we must wait for a larger number of cases before deciding this question."

Of the twenty-five deaths met with by Martin in his first eighty-four cases, fifteen died of "bleeding, embolism, and collapse," all of which, of course mean hæmorrhage. Now by the extra-peritoneal method, these would all have been saved, as bleeding cannot possibly occur if the wire does not slip or break. Again, ten of Martin's cases died of sepsis; this also is much less likely to happen by the extra-peritoneal method, as all cut surfaces are outside the peritoneal cavity, in plain sight, and under perfect control.

When Martin has finished his operation and drops the stump, as I have seen him do, the appearance to the naked eye is simply perfection, and one carries away the feeling that everything is cleaner than the stump of an ovariectomy. On the other hand, when the stump is left outside, as I was taught by Bantock, the after-treatment is often tedious, and the convalescence prolonged. If the stump is not perfectly dry it is apt to suppurate, and, at best, it is an unsightly affair. But when we contrast the results, there can be but one choice, if we give proper consideration to the safety of our patients. Not only are Martin's own results bad, but in the hands of less expert and experienced operators the mortality is very high. Even Bantock has lost four out of five cases by the intra-peritoneal method. By the extra-peritoneal method, five or six of us here in Philadelphia can now put on record twenty or more cases with only about two deaths in the lot, and those were cases in which there was extensive cancerous involvement of vital organs. In fact, our mortality is about as good as that in ovariectomy.

The use of electricity in fibroids is not without

its dangers and impossibilities. Such a case as that before you is wholly beyond the reach of this palliative agent. To have done any good to that tumor it would have to be punctured, and this large cyst which you see, emptied. To have done so in this case would have required a puncture four or five inches deep; the needle would have to have penetrated the whole length of the tumor. Dr. Massey punctured one of these cystic tumors (if I recollect correctly) last winter, and the patient very promptly died of sepsis. At the June meeting of this Society Dr. Price presented two specimens of fibroid tumors. One was a large œdematous myoma, containing blood vessels as large as the iliaes, and as he then said, one might as well have tried to dissipate the iliaes themselves as those vessels; a puncture of any one of them would have meant tremendous hæmorrhage. The second specimen was a fibro-cystic tumor with nothing but a thin membrane between the cyst cavity and the uterine cavity, the membrane being lined with a mass of blood-sinuses as large as one's little finger. An attempt to puncture that case would have meant almost instant death. And so it is with many other specimens on record. The fact is plain that there is a large class of fibroid tumors totally unfit for the electrical puncture; and to make the danger in these all the greater, they cannot always be differentiated. For instance, the fibro-cystic character of the specimen before you was not even suspected during life, although repeated examinations were made. There is plenty of material here for earnest thought, and it ought to be a warning against blindly rushing into the use of electricity in all cases, simply because the enthusiastic advocates of this treatment fail to bring out its dangers, and, in fact, only too universally hide them.

## FOREIGN CORRESPONDENCE.

### LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

*Some Interesting Facts about the Brain—Poisoning by Arsenic—The Overcrowding of the Medical Profession—Statistics of Admission to Scottish Lunatic Asylums—The Mode of Treatment at Aix les Bains—The Anglo-American Vienna Medical Association—Miscellaneous Notes.*

There has been published the result of some measurements of the heads of students in the Cambridge University, showing that although it is pretty well ascertained that in the masses of the population the brain ceases to grow after the age of 19 or even earlier, it is by no means so with University students, and that the men who obtain University honors have larger brains than the average. Further careful experiments show

that the brains of human beings change in size. Taken at different times in the same individual the length of the head varied  $\frac{1}{8}$  inch, the width  $\frac{1}{8}$  inch, and the length as much as  $\frac{1}{2}$  inch. The variations were not due to head growth. They sometimes showed reduction of size to the extent of 6 per cent.

In a recent discussion upon "Poisoning by Arsenic," it was generally admitted that acute cases followed by urgent symptoms and death were best known in the practice of forensic medicine, but arsenic could be administered as a slow poison, and death might occur six weeks after the victim had ceased taking arsenic. Nevertheless the symptoms are much the same in both cases, varying only in the time of development. There are first troubles of the digestive organs; secondly, catarrhal bronchial irritation and eruptions on the skin; thirdly, loss of sensibility, numbness of the lower limbs, cramps, acute pains, followed by local insensibility; and the fourth and final stage is indicated by paralysis. The case was mentioned of a woman who was poisoned at Havre, and whose hair was cut and analyzed. One hundred grams of her hair yielded 1 milligram of arsenic. It was thought that there should be no difficulty in detecting arsenical poisoning if the bones and especially the cancellous tissue was analyzed.

During the long vacation just ended many journals have taken the opportunity to warn intending students of medicine that the ranks of the profession are at the present time tremendously overcrowded, and that it was impossible for them all to make an adequate livelihood. For the last five years an average of 1,921 entering medical students have annually registered their names, which shows if competition has been severe in the past, it is certainly to be more so in the near future. At his opening lecture Dr. P. S. Abraham, at the Westminster Hospital, referring to the progress made in the medical profession, said the "barber surgeon" was long since extinct and the hybrid medical tradesman was becoming obsolete, and that Voltaire's oft-quoted dictum that a medico "was a man who poured drugs of which he knew little into a body of which he knew less" was not quite so true now as it was. He pointed out the fact that London was the healthiest city in the world, as a concrete result of the attention paid to the advice of sanitarians. He admitted that in recent years the State had more and more recognized its obligations to the public weal and had done much for the science of health, but a great deal was still left to private effort and generosity. They had to await the initiation by his Royal Highness the Prince of Wales and his "Damien Committee" of a much needed crusade of investigation against one of the most terrible scourges of mankind, and they had to leave gaps in their knowledge of an important therapeutic

agent until an enlightened Indian prince came forward and handsomely defrayed the cost of its re-examination.

Statistics of admission to Scottish lunatic asylums indicate an unmistakable seasonal variation. The Report of the Commissioners contains a table showing the numbers for each month of the eight years 1880-1887. The average monthly total is 1,699, but during the three months of May, June and July that average is exceeded by 628, while in the four months of October, November, December and January the admissions are 462 below the mean. These two periods of maximum and minimum are the extremes of a regular annual rise and fall. A steady increase is perceptible through February, March and April, and after the culmination in June there is a similar fall from July to the autumnal equinox. Similar figures collected for the years 1865-1874 reproduce exactly the same periodical change, differing only in the length of the maximum in early summer. Another fact which points to the same conclusion is revealed by the statistics of suicides, for Mr. Buchan and Dr. A. Mitchell showed long ago that self-murder was most common in just those very summer months in which lunacy is most rife.

Many patients are now returning from Aix-les-Bains. The patient at this health resort has to go through a somewhat curious course. He walks down—unless rheumatics have crippled him too much—to the bathing establishment in the morning. There he is shampooed and massaged, but he is not allowed, as in most places, to go home in his own clothes. He is wrapped up in blankets, is then deposited in something resembling the old sedan chair, is carried by two stout porters back to his room and put to bed. There he has to remain for some time perspiring copiously and, if possible, sleeping. In some cases there is a renewal of the massage. The patient at Aix-les-Bains is nearly always tired and always depressed, but people who have tried the place for many years describe its results as miraculous.

In Vienna some English and American physicians have resolved to found a society to be called the Anglo-American Vienna Medical Association. The society is founded with a view to giving information and moral support to the English and American doctors and students of medicine who come to the Vienna University. As a rule there are but few students of medicine from England and America, but a great number of doctors of medicine. In the last half year 105 American doctors and several lady doctors were on the books.

At a meeting of the Society for the Study of Inebriety, held in the rooms of the Medical Society of London, Dr. Norman Kerr, the President, stated that though he had known arsenic, iodine and similar substances to make a permanent im-

pression on the nerve centers, and taken habitually to excess, he could not class arsenic eating alongside of alcoholism or morphinism as a true narco-mania or inebriety. It was resolved to ask for a Parliamentary committee of inquiry into the Inebriates Acts, with a view to amend legislation.

The many Americans and others who winter in Venice will be pleased to hear that the town is to undergo a complete sanitary rehabilitation. The works to be commenced with this object will spread over ten years, and the first provisional estimate of the outlay amounts to some four and a half million francs. In conjunction with this purely hygienic undertaking a plan for remodeling the city architecturally will also be carried out, for which a period of thirty years is computed to be necessary.

Lady Milne has died at a dentist's in Edinburgh whilst under the influence of gas for the purpose of having a tooth extracted.

## DOMESTIC CORRESPONDENCE.

### Tetanus Caused by Intestinal Irritation.

*To the Editor:*—Whilst looking over THE JOURNAL of September 7, 1889, I noticed a letter from P. B. P., of New York, giving a synopsis of a paper on "Tetany in Infancy and Early Childhood," read by Dr. J. Lewis Smith at the last meeting of the New York County Medical Association, which alleged that there is no recorded instance in which lumbrice or ascarides caused tetanic contractions: but Gowers refers to three cases caused by tapeworms. This statement of Dr. Smith's brings to my mind the case of Sarah Shelton (colored), aged 12 years, which occurred in my practice a few years since. I was summoned during the month of February to see this patient, who was suffering with the most violent attack of tetanus that I had ever seen. I found her resting upon her head and heels in a state of complete opisthotonos, with the jaws firmly closed and the head drawn to the left side. Every muscle in her body seemed to be rigid except those employed in deglutition. Her arms were forcibly flexed, and the muscles of the abdomen were as hard as a brick. After a careful examination I found that there was no traumatic injury, and I at once suspected that worms in the alimentary canal were the cause of the trouble, and calomel and santonine were given in decided doses, followed by castor oil and turpentine. Her bowels were obstinately constipated and refused to respond to this treatment. Enemas were then given, upon which she passed a large ball of lumbricoids containing about thirty worms, half of which were dead. Her muscles would relax only

when under the influence of chloroform administered by inhalation. The bromides, chloral, Indian hemp and morphia were also used, but they gave only temporary relief. Finally I gave her the tincture physostigmatis, prescribed a generous diet with stimulants, and an occasional laxative. She remained in this rigid condition more than a month, but she is now as healthy and well developed as any young woman in this county. I was fully convinced then, and am now, that this species of worms was the specific cause of her condition. If you consider this case of sufficient interest you have my permission to give it a place in your excellent journal. Respectfully,

B. A. DUNCAN, M.D.

West Point, Miss., October 11, 1889.

### One Cause of Sickness and Discomfort Largely Preventable.

*To the Editor:*—Owing to the drouth, fires, especially in swampy places, are numerous, and the atmosphere is unusually smoky and irritating to the eyes, head and air-passages. Some diseases are aggravated,<sup>1</sup> sleeplessness, nervous disturbance, general discomfort and, I believe, other serious troubles not commonly recognized, as due to this cause, result, because the atmosphere is to a considerable extent unfitted to properly sustain life. One apparent change in the atmosphere is to lessen, below the normal limit, the active oxygen, and this is especially true during the nights; thus, during the week ending October 19th no ozone whatever could be detected in the atmosphere at Lansing on any night except one, Wednesday. A sense of want of air, even approaching suffocation, and a weakness of the circulation, in some approaching heart failure, has been noticed.

The object of this note is to ask attention to the fact that much of this discomfort and danger to health could easily be prevented if all persons would refrain from setting fire to rubbish until after this bad condition of the atmosphere has passed. On some evenings dozens of such fires have been set in one small city in the interior of this State. "As the wind goes down with the sun," nearly all the irritating smoke and bad air from such fires built in the evening remain in the city or village, and must be breathed by the inhabitants.

If such fires must be made, it would be very much better to build them in the morning, because the movement of the atmosphere then usually increases until 2 P.M., and that may carry the foul and irritating air from such burning rubbish outside the city or village.

HENRY B. BAKER, Secretary.

Office of the State Board of Health, Lansing, Mich., October 23, 1889.

## NECROLOGY.

### Morse K. Taylor, M.D.

Morse K. Taylor, M.D., late Surgeon U. S. A., died at his residence in San Antonio, Texas, on the 20th of October, 1889, after an illness of two weeks.

Dr. Taylor was born in Watertown, N. Y., on May 14, 1823. He subsequently moved into Michigan, where he commenced his military life as Second Lieutenant in the First Michigan Cavalry, and served through the war with Mexico with credit and was honorably discharged in July, 1848. After his discharge he commenced the study of medicine and graduated from the medical department of the University of Michigan at Ann Arbor in 1852, and soon commenced the practice of his profession in Galesburg, Ill. On the organization of the Chicago Medical College, then called the Medical Department of Lind University, in Chicago, 1859, he was appointed to the chair of Physiology and Hygiene in that institution. He discharged the duties of that position with ability and to the satisfaction of both faculty and students, but only two years later, 1861, the war for the preservation of the Union commenced, and he was offered the position of Colonel of the Fourth Illinois Infantry.

This he declined and accepted the office of Surgeon of the Twenty-sixth Illinois Infantry in August, 1861. The next year he was commissioned Surgeon of United States Volunteers, and served in that capacity until October, 1865, when he was honorably mustered out, having been promoted to the rank of brevet Lieut.-Colonel for faithful and meritorious services. The war having closed he settled in Keokuk, Ia., and commenced practice.

In May, 1867, however, he was commissioned Captain and Assistant Surgeon in the United States Army, and was assigned to active duty on the Western frontier. He continued in active service in different places in the West until 1879, when he was transferred to New York, next to Detroit, and afterwards to Fort Sill, in the Indian Territory, where, in 1884, his wife died, to whom he had been married at Clinton, Mich., April 25, 1849. In June, 1882, he was made Surgeon with the rank of Major, and on the 14th of May, 1887, he was retired from active service, having reached the age of 64 years, and ordered to San Antonio, Texas, the place he had chosen for his residence. Here he identified himself with all the more important interests of the community, social, educational and religious, and won the respect of all.

He was a physician of marked ability and scientific attainments; an active member of the American Medical Association, and an accurate writer.

<sup>1</sup> During the week ending October 19th, tonsillitis increased 50 per cent., pleuritis 33 per cent., inflammation of the brain 25 per cent., and membranous croup 25 per cent. Probably other causes than the one here mentioned had influence, but the other atmospheric conditions were not such as to account for such increase.

A correspondent at San Antonio says: "He had in process of completion a work on the climatology of Texas, which for scope and detail is wonderful." His son, Dr. F. M. Taylor, has been intimately associated with him in his more recent literary and professional work, and it is hoped that he may complete the same for the public.

N. S. D.

### Thos. Snowden, M.D.

Dr. Thomas Snowden, a resident of Peekskill, N. Y., died in New York City October 11, æt. 64 years and 8 months. He was an alumnus of the College of Physicians and Surgeons, New York—a member of the class of 1849.

## MISCELLANY.

COMPARATIVE OBSTETRICS.—A giraffe has been born in the Cincinnati Zoo, the first delivery of this kind that ever took place in this country. It is said to have been a head presentation and to have been a long labor, the baby being nearly 6 feet from tip to toe when dropped.

THE AMERICAN ACADEMY OF MEDICINE will hold its thirteenth annual meeting at the Leland Hotel, Chicago, Ill., on Wednesday and Thursday, November 13 and 14, 1889. Papers will be read as follows:

"Object, Scope and Mission of the Academy," Drs. Traill Green, of Easton, Pa., Edward Jackson, of Philadelphia, and R. Lowry Sibbet, of Carlisle, Pa. "Literary Degrees as they Interest the Academy," Dr. Richard J. Dunglison, of Philadelphia, Pa. "Preliminary Requirements of American Medical Colleges of the Present Time," Dr. John H. Rauch, of Springfield, Ill. "Instruction by Recitation," Dr. Henry M. Lyman, of Chicago. "Methods of Teaching Medicine," Dr. Wm. F. Waugh, of Philadelphia. "Medical Harmony, as Influenced by Preliminary Training," Dr. F. C. Heath, U. S. M. H. S., Detroit, Mich. "Professional Integrity vs. the Code," Dr. S. N. Benham, of Pittsburg, Pa. "The Institutes of Medicine; the Necessity of Their Being Taught in Our Schools," Dr. J. Cheston Morris, of Philadelphia, Pa. "Gymnastic Medicine," Prof. E. Hitchcock, Jr., M.D., of Ithaca, N. Y. "Vice and Crime," Dr. J. A. Thacker, of Cincinnati, O. "The Moral Treatment of the Insane," Dr. Gersham H. Hill, of Independence, Ia. "Sulphonal in Hysteria," Dr. Andrew C. Kemper, of Cincinnati, O. "The Physiological Action of the Typhoid Fever Poison," Dr. N. S. Davis, Jr., of Chicago. "Malignant Tumors of the Mammary Glands, with Cases," Dr. E. F. Wilson, Columbus, O. "Improved Operation for Varicocele," Dr. E. Wyllis Andrews, of Chicago. "What is the Proper Function of American Medical Colleges of the Present Time?" Dr. Samuel J. Jones, of Chicago, Ill.

Reports will be read from various special and standing committees; among the latter, one by Dr. Justin E. Emerson, of Detroit, Mich., on "Preliminary Requirements of Medical Colleges," and one by the Secretary of the Academy, Dr. Dunglison, on "Laws Regulating the Practice of Medicine."

The President's address will be delivered by Dr. Lear-tus Connor, of Detroit.

The annual collation will take place at the Leland hotel on Wednesday evening, November 13th.

RICHARD J. DUNGLISON, M.D.,  
Secretary.

### *Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 26, 1889, to November 1, 1889.*

Major Morse K. Taylor, Surgeon U. S. A. (retired), died October 20, 1889, at San Antonio, Texas.

Major Robert M. O'Reilly, Surgeon, par. 3, S. O. 24, October 16, 1889, from this office, is so amended as to grant him leave of absence for six months, with permission to leave the United States, by direction of the Secretary of War, to take effect November 1, 1889. Par. 6, S. O. 252, A. G. O., Washington, October 29, 1889.

By direction of the Secretary of War, so much of par. 2, S. O. 44, October 16, 1889, from this office, as relates to Lieut.-Col. Anthony Heger, Surgeon, is amended to read as follows: Lieut.-Col. Anthony Heger, Surgeon, is relieved from further duty in the Div. of the Atlantic, and will at once report to the Major-General commanding the Army for duty in this city. Par. 3, S. O. 252, A. G. O., Hdqrs. of the Army, October 29, 1889.

Major Joseph R. Gibson, Surgeon U. S. A., granted leave of absence for seven days, to take effect from date of being relieved from duty at Ft. Sheridan, Ill. Par. 9, S. O. 249, A. G. O., October 25, 1889.

By direction of the President, Major Wm. H. Forwood, Surgeon, is detailed as a member of the Army Retiring Board at St. Paul, Minn., convened by War. Dept. order dated January 12, 1889, published in S. O. 10, January 12, from Hdqrs. of the Army, vice Capt. Edgar A. Mearns, Asst. Surgeon, who is hereby relieved. Par. 12, S. O. 254, A. G. O., October 31, 1889.

By direction of the Secretary of War, so much of par. 10, S. O. 242, A. G. O., October 17, 1889, as directs Capt. Louis M. Maus, Asst. Surgeon, to report in person for duty at Ft. Stanton, N. M., to relieve Capt. Marcus E. Taylor, Asst. Surgeon, is revoked, and Capt. Taylor will proceed to Boise Bks., Idaho Ter., as directed in said order, as soon as medical attendance shall be provided for Ft. Stanton. Par. 10, S. O. 249, A. G. O., October 25, 1889.

By direction of the Secretary of War, Capt. Wm. C. Gorgas, Asst. Surgeon, is relieved from temporary field duty in the Dept. of the Missouri, and will join his proper station (Ft. Barrancas, Fla.). Par. 2, S. O. 25, A. G. O., October 28, 1889.

Capt. Louis M. Maus, Asst. Surgeon U. S. Army, granted leave of absence for two months on surgeon's certificate of disability. Par. 11, S. O. 249, A. G. O., October 25, 1889.

First Lieut. Julian M. Cabell, Asst. Surgeon U. S. A., granted leave of absence for two months, on surgeon's certificate of disability, to take effect about November 10, 1889. Par. 7, S. O. 249, A. G. O., October 25, 1889.

#### APPOINTMENTS.

First Lieut. Charles Willcox, Asst. Surgeon U. S. A., to rank from October 29, 1889.

First Lieut. Harlan E. McVay, Surgeon U. S. A., to rank from October 29, 1889.

First Lieut. E. B. Frick, Surgeon U. S. A., to rank from October 29, 1889.

By direction of the President, the Army Retiring Board convoked at Vancouver Bks., W. T., by War Dept. order dated December 15, 1888, published in S. O. 292, December 15, 1888, from Hdqrs. of the Army, is dissolved. Par. 1, S. O. 230, A. G. O., Washington, October 26, 1889.

### *Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 2, 1889.*

P. A. Surgeon F. S. Nash, detached from duty in Bureau Med. and Surg., and to the "Petrel." November 14, 1889.

Medical Inspector E. S. Bogert, ordered to examination preliminary to promotion to Medical Director.

Asst. Surgeons O. D. Norton, I. W. Kite and E. P. Stone, ordered to examination preliminary to promotion to P. A. Surgeon.

### ADVANCES IN OUR KNOWLEDGE OF SOME CEREBRAL, OCULAR, AND IN- TRA-ORBITAL LESIONS; WHICH FACILITATE THE DIAGNOSIS AND TREATMENT OF IM- PORTANT DISEASES.

*Read in the Section of Ophthalmology, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY HENRY W. WILLIAMS, A.M., M.D.,  
OF BOSTON.

PROFESSOR OF OPHTHALMOLOGY IN HARVARD UNIVERSITY.

In offering a short paper to the Association I assume that knowledge independently acquired in a special department of practice may be a useful contribution to the general store; especially if illustrating the importance of an adequate theoretical and clinical training in order that the value of local phenomena, and their relation to coexisting conditions of other organs and of the general system, may receive due estimation. Much of our information, on points to which I am to refer, is of so recent date, that I trust a brief epitome of some personal observations may not be unacceptable.

#### INTRA-CRANIAL GROWTHS.

When we remember that less than forty years ago the existence of intra-cranial growths was usually but dimly suspected from the existing symptoms, and only rarely demonstrated at autopsy; and that we are mainly indebted for the first and most positive recognition of their presence, to the disclosures revealed through the medium of the ophthalmoscope, with which we were endowed in 1851 by Helmholtz, we may well congratulate ourselves on the brilliant advances in cerebral pathology and cerebral surgery which his invention has done so much to render possible; as well as on the vast increase of our knowledge of intra-ocular lesions obtained through its assistance. These results afford a striking instance of the direct application of purely scientific investigations to the benefit of man.

But while being thus enabled to assert the existence of intra-cranial growths, we did not at once recognize the full therapeutic importance of

this newly acquired knowledge. Unable at first to discriminate between those specific formations which are often amenable to constitutional treatment, and those of local origin, or to determine accurately the position of the lesion, we often looked on helplessly while the disease went on to its sad termination.

I offer a few instances from my own experience as a contribution to the symptoms and history of early recognized cases which were uninterrupted in their course and were verified by autopsy.

Soon after the addition of the ophthalmoscope to our optical resources, I saw in consultation a gentleman in middle life, on account of loss of vision. The diagnosis of cerebral tumor was made. As the disease advanced the senses of taste and smell were also gradually abolished, and death occurred about six years from the invasion of the disease. The tumor, which was shown to me, was of about the size of a man's fist. Not long afterwards, another gentleman of similar age came under my care, in whose eyes the condition of the optic disc and retina justified the same prognosis, and led me to predict a probable eventual failure of other senses, in addition to the loss of sight—which result slowly ensued. Two distinguished New York *confrères* confirmed my opinion. Despairing of aid from our profession, the patient was induced to place himself in the hands of charlatans, whose sanguine promises of relief were followed by no other results than the copious depletion of his purse, and at last he came again under the care of his family physician. The autopsy disclosed an enormous cerebral tumor, slowly formed during the six years' continuance of his disease, and which I had an opportunity to examine.

A middle-aged clergyman was brought to me by his physician, on account of failure of vision without marked cerebral or other symptoms. Surprised at my prognosis of a fatal result, as indicated by the ophthalmoscopic evidences of optic neuritis caused by cerebral tumor, his attendant asked what might be expected as to the duration of life. I said six months seemed to me a probable estimate, although it was impossible to predict with certainty. Death occurred three days beyond the above named period.

In the case of a stout middle-aged woman whom

I saw from time to time for six months, the diagnosis was made very early, but there were no severe symptoms until a short time before the fatal termination. At the post-mortem we found a tumor no larger than a filbert, at the base of the brain, surrounded by softened cerebral substance.

A *confère* came a long distance to see me, accompanied by his physician. He had only moderate pain and lessened vision, but no diminution of intellectual or physical vigor to any great extent; although, when I made the diagnosis of optic neuritis caused by intra-cranial growth, perhaps in the cerebellum, his friend agreed with me that this explained his symptoms better than any other theory. The patient returned home, seemingly little fatigued by his journeys, but died three weeks afterwards. The tumor, found in the cerebellum, was sent to me for inspection, and was of the size of a pullet's egg.

I have seen but one instance in which the morbid ophthalmoscopic appearances were monocular: a case of a young gentleman from a Western city, who complained of lessened vision in his left eye, with a moderate degree of pain about the left temple and supraorbital region. The ophthalmoscope disclosed optic neuritis, associated with retinal hæmorrhage in the left eye; the right eye remaining normal. These phenomena, with the localization of the pain, led me to make a diagnosis of tumor between the left eyeball and the optic chiasma. Little increase of symptoms or change of ophthalmoscopic appearances occurred for some weeks; until, about a fortnight before death, the pain became greatly aggravated and extended to the eyeball itself, with much depreciation of vision. At the post-mortem I found a tumor of the form and size of a large olive, which, lying upon the supraorbital plate, had gradually caused its erosion and, at last, perforation; so that the tumor had come to press upon the eyeball, and thus to occasion the sudden increase of pain and loss of vision. There is reason to believe that had cerebral surgery been at that time in vogue, my patient might probably have been saved, and possibly his vision improved, by an early trepanation.

I cite some of these cases, in which post-mortem verification was obtained, as showing the varying character and course of the symptoms of intra-cranial tumors. The details as to their microscopic structure and the relative frequency of the different forms, as well as the coexisting functional disturbances which aid in determining the localization of the morbid growths, have been fully set forth in the results of the admirable researches of v. Graefe, Allbut, Ferrier, Hughlings Jackson, Gowers, Bramwell, Horsley and other observers. These frequently enable us, by a comparison of the indications afforded by the existing local signs, the appearances seen with the ophthalmoscope, and the varied derangement of nerve

action, to designate with great accuracy the position of these intruding growths, and to estimate their development; and thus, in a large proportion of cases, we may obtain data which enable us to decide whether the conditions are such as to justify operative measures, or whether these would be inexpedient; or if reabsorption of masses having a specific origin may not, perhaps, be obtained by constitutional remedies.

We have seen that the symptoms in different cases vary greatly in intensity; not always corresponding with the size or rapidity of growth of the neoplasm, but rather with its situation and its relations to important parts. Cases now and then occur where these symptoms are very slight or even absent, and the lesion is only discovered after death. The same is true, exceptionally, as regards the characteristic ophthalmoscopic signs. Although, when present, these peculiar forms of optic neuritis and retinal apoplexy afford perhaps the most conclusive evidence of cerebral tumor, yet these are occasionally lacking, where other indications of tumor exist; or their stage of acute engorgement may subside, to be followed by atrophy of the opticus and of the retinal vessels. Even where these changes are observed in a marked degree vision is not always materially or permanently affected. But though so valuable in disclosing the existence of morbid intra-cranial growths, the ophthalmoscope seldom affords a clue as to their position, which must be determined by the concurrence of other local and general symptoms; such as limited headache, as tenderness on percussion of the skull, vertigo, paralysis or paresis of motor nerves of the eyeball or other cranial nerves—which often indicate with great exactness the situation of the neoplastic growths.

Doubtless cerebral surgery will become more and more precise and the proportion of successful operations larger, as experience determines with yet greater exactness what intra-cranial growths are and what are not amenable to surgical treatment, and what improvements may give the best results in the removal of what would be otherwise invariably fatal lesions.

#### INTRA-OCULAR CONDITIONS HAVING IMPORTANT RELATIONS WITH OTHER DISEASES.

Only a generation ago the suggestion that we should look into the depths of the eye to detect the presence of Bright's disease, meningitis, malaria, lead poisoning, of syphilis, of a tendency to apoplectic effusion, of albuminuria in pregnancy, or of post-partum pyæmia, would have been deemed in the highest degree chimerical;—but these, as we know, are but a few of the many lessons we may read in the retina, the optic disc, the choroid and the vitreous, by means of Helmholtz's ophthalmoscope. Not the least of the brilliant services of this instrument is its afford-

ing the proof, through its revelations at the fundus of the eye, that myopia, or near-sightedness, is not merely an inconvenient infirmity, but, in its higher degrees especially, a serious disease, having progressive tendencies and a disposition to hereditary transmission; and, moreover, that this is a disease of civilization, created or enhanced by inordinate use of the eyes in minute work. It is to be hoped that the profession may at length be able to induce ambitious parents to accept their advice as to moderation in regard to continued close application of the eyes of their children, as the only means of safety; and thus to prevent the too frequent impairment and even the ultimate loss of vision as a sequel of excessive study during the growing period, to which is so often sacrificed the most precious of the senses. In these cases, unfortunately, the victim has no other warning than our admonitions. This makes it the more important that the educated and the educating public should understand that preventive advice is the only resource at our command, and that grave alterations in the retina, choroid and vitreous, once induced, cannot be removed by treatment.

I was the first to propose, in 1853, the systematic substitution of early and continuous dilatation of the pupil by means of mydriatics in cases of iritis, in place of the indiscriminate administration of mercury which had been previously regarded as the only method of preventing occlusion of the pupil by plastic deposits in cases of this disease. I showed, in a report of more than sixty cases, that the effused lymph was reabsorbed, within a brief period, without the use of a particle of mercury, provided that adhesions of the margin of the pupil to the anterior surface of the crystalline had been prevented by free and constant dilatation; but that no amount of mercurialization would produce absorption, if these adhesions were allowed to form in default of the use of mydriatics. This method of treatment, of what may be regarded as to a large extent a self-limited disease where complications from effusions have been averted, has been largely accepted by the profession; to the great relief of thousands who in consequence of a rheumatic diathesis are subject to repeated attacks of iritis, and who are now spared the liability to persistent sialogical effects which so often rendered the mercurial remedy worse than the disease.

There is reason to believe, moreover, that this demonstration of the possibility of dispensing with a potent agent which had been regarded as absolutely indispensable in a frequently recurring disease, has had an influence in lessening the lavish resort to mercury as a panacea in almost every affection of the system. The report of Dr. Hughes Bennett, of Edinburgh, chairman of a committee of the British Medical Association to investigate the action of mercury on the secretion of bile,

showed, as the result of experiments on dogs, that the flow of bile was not increased, as had been supposed, by the administration of mercury; but was, on the contrary, lessened. The published results of my experience were quoted by Dr. Bennett as affording evidence that the vaunted powers of mercury in promoting the removal of plastic effusions, which had for a long period been accepted as unquestioned, had, to say the least, been exaggerated; and he suggested that two cherished beliefs as to the *modus operandi* of this powerful drug in so very general use were perhaps without adequate foundation.

#### PHLEGMONOUS INFLAMMATIONS OF THE ORBITAL TISSUES AS A SEQUEL OF FACIAL ERYSIPELAS.

The last subject to which I ask attention, is the insidious formation of deep-seated intra-orbital abscesses; especially as a sequel of facial erysipelas. Until 1881 I had not seen nor read an account of a case of this sort; although Graefe had already mentioned its occurrence. In that year I saw in consultation a *confière* who was convalescing from a severe attack of erysipelas, affecting the scalp, forehead, neck and face. The lids of left eye were still much tumefied and two abscesses had formed in the upper and one in the lower lid. A deep-seated abscess also formed in the cheek, near the ala nasi. These I opened, and there was a rapid lessening of swelling of the lids and of the serous chemosis which had formed upon the globe. All was apparently going on well, and vision was tested daily and found perfect. For two weeks there was gradual improvement, so that the lids opened and everything promised a speedy recovery. Suddenly I found one morning, at our visit, the chemosis more marked; the globe was rotated with difficulty, and vision, which had been good the previous day, was found to be wanting. There was a sense of discomfort in the region of the outer canthus. The ophthalmoscope showed slight indistinctness of the optic disc, a slight lessening in calibre of the retinal vessels, and a faint yellowish-gray aspect of the fundus of the eye. Without other indications than these mentioned, I expressed the opinion that a purulent nidus must have formed in the post-ocular cellular tissue, probably towards the outer side of the orbit. It was agreed that, after etherization, puncture should be made in the region most complained of. I accordingly made two punctures with a long and narrow Graefe knife, going carefully to the posterior wall of the orbit, a depth of more than 2 inches, without finding pus. No further attempts were thought then to be proper. On the following morning, the indications continuing as before, three more deep exploratory punctures were made; from the last of which pus was reached. Drainage was established, and a moderate flow continued for three or four days. Recovery was favorable as regarded a normal as-

pect and movements of the eye, and with no noticeable atrophy of orbital cellular tissue; but there remained absolute loss of vision. The grayish-yellow aspect of the fundus, which at first led me to apprehend a possible supervention of suppurative choroiditis, slowly gave place to a slightly atrophic look, but the disc did not assume a chalky white appearance, as in ordinary atrophy of the opticus.

My presumption was, that the inflammatory processes, terminating in infiltration and abscess, must have compressed and partially obliterated the retinal vessels in their passage from the optic foramen through the orbit, and previous to their entering the optic nerve to go to the retina. The early evacuation of the abscess prevented the pus from making its way backwards through the foramen or from so far protruding the eye forwards as to cause sloughing of the cornea and phthisis bulbi; but was not in season to admit of restoration of the retinal functions.

As sometimes happens with unusual cases, this first instance seen after many years of practice was succeeded by several others grouped within a brief period; in all of which, taught by this experience, and having the good fortune to see them early after the invasion, I was able to evacuate the purulent deposit before vision had been permanently damaged or other serious results had ensued.

Soon after my first case was seen, a history of seven cases was collected and published by a German observer; of which five were fatal to life, from meningitis following infiltration into the cranial cavity.

One of my cases was interesting as having occurred during convalescence from erysipelas in a boy 9 years of age, whose vision had already become so far affected when I saw him in consultation, that objects appeared red to the eye on the implicated side. Evacuation of the very deep-seated pus was followed by recovery of normal vision.

An interesting case of deep orbital abscess, not preceded by erysipelas, was ascribed by a patient, a vigorous man of middle age, to exposure to intense cold during sleep in the open air. When seen late one evening I was enabled to determine the diagnosis, but the abscess was not reached by an exploratory puncture, although considerable relief from tension was obtained. A repetition of the incision on the following day was effectual, and rapid recovery, without damage to vision, followed the establishment of drainage.

Gradual accumulation of pus in the orbit, as a sequel of necrosis of the orbital parietes, offers less acuteness of the symptoms; and this, as well as the idiopathic and partial phlegmon of the orbital cellular tissue not very rare in young children, involves less danger to life and to vision than the acute attacks above described as supervening upon erysipelas, or than such as are due

to pyæmic infection of the circulation, which usually terminate fatally. Purulent inflammation within Tenon's capsule is usually severe, and may result in loss of vision, but does not involve other dangers, as the pus generally tends towards the surface, between the insertions of two of the recti muscles. It is fortunately rare, and if early detected should be at once evacuated to afford a chance of preserving vision.

The urgency of an early diagnosis and of prompt operative interference in cases of orbital phlegmon cannot be too much insisted on. Of forty-four cases collected from all countries by Dr. A. Schwendt, of Basle, loss of vision, from amaurosis or from phthisis bulbi, occurred in about 80 per cent., and the proportion of fatal cases was 25 per cent. of the whole number, including the more benign cases resulting from orbital caries.

DR. KNAPP, of New York, said that there was a considerable literature on the orbital cellulitis and that he had collected it on the occasion of a typical case which he published in the *Archives of Ophthalmology*. The case was observed from its beginning. When the orbital tissue was completely infiltrated, the eyeballs protruded and were totally immovable, the ophthalmoscope discovered the veins large, tortuous and black, the arteries apparently absent, in reality invisible because of being empty, and very numerous dark-colored retinal hæmorrhages. In less than a week the orbital tissue became less hard, the retinal arteries were visible again and there was a new set of hæmorrhages, which were light red. The contents of the black veins showed the gradual conversion of the black thrombi into white ones, which appeared first in white sharp-cut lines, interrupted by dark red ones, which also became white, and the termination was atrophy of the optic disc, the retina and choroid, with the retinal vessels as white lines. The supposition that the ophthalmoscopic picture is best explained by compression of the orbital vessels, became much more plausible when we learned that the micrococcus erysipelatis (Fehleisen) invades by preference the lymphatics, in particular the perivascular lymphatic spaces.

I would like to point out two kinds of optic neuritis that give a relatively favorable prognosis. I mean that in children, and that connected with disseminate (alveolar) choroiditis. In the latter variety it commonly appears as a neuroretinitis, but in some cases the picture of choked disc is marked, and apt to alarm us.

DR. CHISOLM reported a case of marked papillitis occurring in a young person æt. 22, whose case was diagnosed brain tumor and treated as such by a skilled specialist and confirmed by a second, who measured the prominence of the congested infiltrated disc. By these two gentlemen the most serious prognosis was given, and early

death expected. The most conspicuous symptom was severe pain in the head, increasing on use of the eyes. No benefit or change in the discs occurring from active treatment, the case came under my care six months afterward. I found woolly discs, but no other evidences of cerebral trouble. There was some astigmatism and, believing that this irregular refraction might be the cause of the constant headache, cylinder glasses were prescribed for constant use and the use of the eyes permitted. Recovery was complete. I have recently seen the patient, after three years' interval. Her health is perfect, her eyes give her no trouble whatever. Her discs are still woolly, but no diagnosis of brain tumor is now believed.

Dr. Chisolm also reported a case of blurred vision following a case of facial erysipelas general to the head, accompanied by severe pain in the head, and for a short period by coma. Upon restoration to sensibility hearing was abolished and sight was much impaired. At no time was there any exophthalmos or indication of orbital cellulitis. Hearing has been restored. The sight, which was good before the attack of erysipelas, has never been restored. The ophthalmoscope reveals a normal fundus, nerve and retina. I deemed the case functional and expect benefit from treatment.

DR. LEARTUS CONNOR said with reference to the inflammation of the meninges in cases of optic neuritis accompanying cerebral tumor, he had observed two cases. In case first marked papillitis was attended by the evidences of cerebral tumor. He had seen three cases of cerebral tumor in which no meningitis was to be found post-mortem to account for the disease of the optic nerve. Case first was a lad æt. 16 years.

## BACTERIOLOGICAL EXAMINATION OF NINETEEN AMERICAN MINERAL WATERS IN THE BOTTLED STATE.

*Read in the Section of State Medicine at the Fortieth Annual Meeting  
of the American Medical Association, June, 1889.*

BY GEORGE MINGES, M.D.,  
OF DUBUQUE, IOWA.

About a year ago there appeared in the *Wiener Medizinische Wochenschrift* (Vol. xxxviii, p. 749) an article by Dr. Reinl, of Franzensbad, giving the results of his bacteriological examination of a dozen bottles of each of four of the most popular European carbonated mineral waters, the deduction being that those waters in the bottled state contained too many bacteria, and that the latter had probably gained admission during the manipulations of filling and corking. Not being able to find any records of similar experiments made on our native mineral waters, I began investigations on a more extended scale about the

beginning of the present year, and continued them up to the present time. I examined 144 bottles of mineral water, including nineteen different varieties, as follows:

1. Saline naturally carbonated: Congress, Empire, Excelsior, Geyser, Hathorn, all from Saratoga, N. Y.

2. Carbonated table waters: Bethesda, Silurian, Arcadian, Henk, White Rock, all from Waukesha, Wis., and all charged with artificial CO<sub>2</sub>; also water from the sparkling spring of Manitou, Col., the natural CO<sub>2</sub> of which is first collected and afterward forced back into the same water, and water from the Salutaris spring of St. Clair, Mich., which is charged with artificial CO<sub>2</sub> after its own natural carbonic acid has been allowed to escape. The Bethesda I also examined in the non-carbonated state.

3. Sulphur water from Blue Lick Springs, Ky.

4. Virginia Buffalo Lithia and Rockbridge alum waters.

5. Chalybeate water from Columbian spring, Saratoga, N. Y.

6. Saline non-carbonated from Colfax spring, Iowa, the Castalian water, and that from Crab Orchard, Ky.

I know that I run some risk of being considered a bacteriomanic, but the tendency of the day is to judge of the purity of drinking water more from its bacteriological than from its chemical examination, and I think that most of you will admit that dyspeptics and convalescents, for whom these mineral waters are more especially intended, and whose stomachs are already weakened in their antizymotic powers, should not ingest more than a certain maximum of bacteria. Besides, we must also bear in mind the remote possibility of infection with pathogenic bacteria.

Bacteriological examinations of a number of European mineral springs would seem to indicate that at the source they are generally practically free from germs, especially when they contain much free carbonic acid. I know of no similar examinations of our native springs *in situ*, but suppose that most of them are as pure as those of Europe, on account of the great diversity in the number of germs shown by different bottles of the same water, probably filled at about the same time. When, for example, we find that one bottle of Empire water contains six bacteria to the cubic centimetre, another 410 mould fungi, and still another over 9,000 bacteria, the conclusion becomes quite forcible that the microorganisms were not originally contained in the water, but gained entrance by subsequent contamination.

Reinl found that the bottled water from the Franzensbader Stefanie Quelle contained, on an average, 152 bacteria to the cubic centimetre, that from the Apollinaris spring 214, that from Giesshübler König Otto Quelle 1,620, and that from Krondorfer Kronprinzessin Stefanie Quelle

2,526. It has seemed to me more correct to compare the different waters, not by the average number of bacteria given by several samples, but by the number of bottles containing more than a certain maximum; and I have, therefore, considered all those bottles contaminated which contained more than 250 microorganisms to the cubic centimetre. Viewed in this light, the first of the above European waters had two bottles contaminated out of a dozen, the second three, the third eleven, and the fourth ten. By using the average number of bacteria in making comparisons we would do great injustice to several mineral waters, for example to the Hathorn, where the average of 28 germs to the ccm., as shown by the examination of five samples, is raised to almost 70,000 by the addition of a single contaminated bottle, while the Blue Lick water shows up fairly well with an average of 1,922 germs to the cubic centimetre, although all the bottles are contaminated.

I am aware of several sources of error in my examinations which I could not avoid. In no case could I determine the length of time a water had been bottled; but we know that the bacteria in water multiply with almost incredible rapidity for a time, after which they again slowly diminish in number. A representative of one of the Saratoga waters told me that they kept their bottles on an average about six months after filling before they shipped them. It would also have been well to allow the colonies to develop for the same number of days in every case; but this was impossible, as in some cases the gelatine was completely liquefied in twenty-four hours, while in others the principal growth did not begin until three or four days had elapsed. Again, I can understand that the amount of  $\text{CO}_2$  must vary more or less in bottles of the same kind of water. Thus, the last bottle I examined, one of Manitou, seemed to contain almost no  $\text{CO}_2$ , and this bottle, perhaps for that reason, was contaminated.

All the bottles containing carbonated water were well corked by machine and wired. The still waters were stoppered more loosely, but the corks of Buffalo Lithia and Rockbridge alum bottles were secured with circular paper seals. The bottles containing Castalian and Crab Orchard water were stoppered quite loosely with conical medicine corks. I wrote to all the springs whose waters I examined for information as to the manner in which bottles were cleansed and the carbonic acid introduced. In most cases I received very courteous replies. The Salutaris, Manitou, White Rock and Hathorn companies use the "Hoyt lightning bottle washer." The bottles for Excelsior, Bethesda and Geyser waters are cleansed by hand; those for Colfax by hand with a brush; those for Congress, Columbian and Empire waters by hand with a chain and gravel; at Blue Lick they use shot, and the Crab Orchard

and Buffalo Lithia bottles are used only new and are merely rinsed. Essentially all these methods amount to the same thing. Boiling or steaming is nowhere resorted to.

In making the examinations the following steps were taken: To prevent any impurity from falling into the bottle during the pulling of the cork, the latter was first wet, after which the dirt was removed from the edges with a penknife. The cork was then wet again and wiped dry. The bottle was violently shaken for several minutes immediately preceding its opening to insure an equable distribution of the germs throughout the water. With a pipette carefully sterilized in an alcohol flame and quickly cooled, two samples, one of 1, the other of  $\frac{1}{2}$  cubic centimetre, were taken from the center of the bottle and transferred to two tubes of liquefied meat-water-peptone gelatine. To prevent any germs which might have collected around the edge of the cotton plug sealing the tube from falling into the gelatine, the plug was pushed in flush with the mouth of the tube and the latter heated in the flame until the cotton was singed before adding the water to the gelatine. Before plating out the mixture the neck of the tube was again sterilized by flame until the whole length of the cotton was singed, and the pouring was done as soon as the tube had become cool. Covered glass dishes were used instead of the ordinary plates, to reduce the possibility of contamination to a minimum, and these had been previously sterilized in the kitchen oven from before breakfast until after the noon-day meal. A number of these coated plates were put into a wet-chamber and allowed to hatch at ordinary office temperature for varying periods of time, according to circumstances, as above set forth. The colonies were counted directly when there were not more than about 500; only when there were very many was their number arrived at by calculation. When there was a marked discrepancy between the number of colonies developed from the two samples taken from the same bottle, the result was not utilized; otherwise the average of the two results was taken.

An examination of the following table shows that, on the whole, the number of bacteria in a water diminishes inversely with the amount of  $\text{CO}_2$  it contains. It also shows that the microbiocidal action of artificial  $\text{CO}_2$  is as great as that of the  $\text{CO}_2$  naturally contained in a water, contrary to the deductions of Leone and Hochstetter; for although the Henk water contains large quantities of bacteria, the Arcadian, Bethesda and Salutaris are among the purest on the list. Sohnke claims that the addition of sodium chloride and bicarbonate neutralizes the inhibitory influence of  $\text{CO}_2$  on bacterial multiplication, but we find that the White Rock water, which is thus prepared, has only one-third of its bottles contaminated, while two of Reinl's natural waters show

respectively ten and eleven bottles out of twelve infected. The germ-destroying influence of  $\text{CO}_2$  is best shown by comparing with each other the Bethesda aerated and non-aerated waters.

Name of water.	No. bottles contaminated out of 12.	No. ccm. of $\text{CO}_2$ to the gallon of water	Average No. microorganisms to 1 ccm.

Crab Orchard . . . . .	12	. . . . .	150,000

As a number of these mineral waters are highly extolled as table waters to be used in large cities, on the supposition that the water supply is there very impure, and as some of the well-to-do people of my native city use one or the other of the Waukesha waters exclusively at their tables, it is worth while to examine the drinking water of Dubuque bacteriologically. The latter is derived from various sources. The city water works supply a large part of the town from a clear spring on the top of the bluffs. A sample of water drawn from the hydrant in my own yard was found to contain 86 germs to the cubic centimetre. We have also a number of artesian wells. A sample from one of these contained but 20 microorganisms to the cubic centimetre. The well and cistern water varied, according to the locality from which it was taken, from 14 to 3,200 germs to the cubic centimetre. As those people who have access to the purest supply of their own city are precisely those who use the mineral waters, further comment is unnecessary.

In order to still further satisfy myself about the rôle played by the manipulations of bottling in contaminating the mineral waters above examined, I made a few control experiments.

Two bottles were carefully washed by hand with shot and hydrant water and rinsed three times with changes of clean water from the same source and allowed to drain, in an inverted position, in a room free from dust. A third bottle was boiled for an hour and allowed to drain in the same way. The three bottles were then filled with hydrant water which had been boiled for an hour and allowed to cool while well covered. Bottle No. 1 was loosely stoppered with a conical medicine cork; into the other two large boiled

corks were driven with a corker. All three were allowed to stand in a warm room for five days, at the end of which time their contents were examined by the method above described. No. 1 contained 100,000, No. 2 500,000 germs to the cubic centimetre. The tighter cork of No. 2 had not prevented contamination. The bacteria had, therefore, probably been in the bottle, and did not enter along or through the cork. No. 3 contained 725 microorganisms to the cubic centimetre; as I had carelessly dropped the cork upon the floor, the contamination was accounted for. I repeated the experiment with a fourth bottle, which was treated precisely as the third had been, except that I was more careful with the cork, and examination at the end of six days showed 66 germs to the cubic centimetre.

#### RÉSUMÉ.

1. The bacteria in bottled mineral waters are probably not derived from the spring, in the majority of cases, but are due to contamination from the bottles and corks, the cleansing methods now in vogue being insufficient to destroy them.

2. Carbonic acid in a bottled mineral water has a powerful inhibitory influence on the development of germs, whether the gas is natural to the water, or has been artificially generated and added to it. When the proportion of  $\text{CO}_2$  is 350 cubic inches or more to the gallon, the retarding influence of the gas is very great. It is much less when the proportion is only 250 cubic inches to the gallon. But among every dozen bottles of even the most highly carbonated waters there is at least one which contains more than 250 microorganisms to every cubic centimetre, and ten even out of twelve bottles may be thus contaminated. When the water is charged artificially some time may be given for contamination before such charging is accomplished.

3. Sulphureted hydrogen gas, in the proportion contained in mineral waters, probably has some inhibitory influences on the development of germs, but not to the extent which might be *a priori* expected.

4. As regards freedom from bacterial contamination, most of our native carbonated mineral waters are superior at least to several of the most popular European waters of the same kind.

5. The non-aerated so-called table waters are probably very inferior to ordinary hydrant water.

6. The strongly saline non-carbonated mineral waters are so badly contaminated as to be wholly unfit for internal administration in the form in which they are at present put up, unless the germs are previously destroyed by heating (for two hours at  $70^\circ \text{C}$ .—Reinl.).

7. In order to bottle at least a non-carbonated mineral water in such a way that it will remain bacteriologically pure for an indefinite period, the bottles should first be boiled or steamed, kept

in an inverted position in a place free from dust until cool, then immediately filled and closed with boiled corks.

## CONGRESS.

No.	No. days growth.	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	12	2		
2	2	2

No.	hrs	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	2	8	Moulds.	
2	3	About 15,000	Small, circular.	
3	3	About 25,000	Small, circular, yellowish-gray, bounded by sharp outline, shaded with short lines.	Strongly curved, active bacilli, 2½ to 3½ m. long and ½ m. broad with rounded ends, variously distorted.
4	3	40,500	1. Small, circular and lemon-shaped, well-defined, greenish yellow, very faintly granular. 2. Large, superficial, grayish, kidney-shaped.	1. Small motile bacilli. 2. Bacilli 1½ m. long and ½ m. wide, single and in twos, motionless.
5	3	45,000	Same as 4.	Same as 4.
6	3	27,500	" as 3, also some of 4-2	

## EMPIRE.

No.	No. days growth.	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	4	410	Principally mould fungi.	
2	13	35	Bacteria.	
3	1	9,689		
4	3	29		
5	2	132		
6	4	45		
7	3½	242	Mostly solid, some liquefying.	
8	2½	51	Bacteria.	
9	2	6		
10	4	125	Light green, circular.	Curved bacilli, alone, also in twos and threes.
11	4	12	Almost all mould fungi.	
12	5	6,103	Mostly small yellowish circular colonies, with sharply defined outline.	Slightly curved bacilli with rounded extremities, 1½-2 m. long, alone and in twos.

## EXCELSIOR.

No.	hrs	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	5	15	Elliptical colonies.	Sluggish, plump bacilli, generally in twos, round ends, 1.65 m. long.
2	6	31	20 per cent. mould, remainder sarcinae.	
3	5	21	Mostly round, solid dark colonies.	Irregular cocci, single, in zoöglea; also in short chains of two and three.
4	5	34	Sarcina, also dark colonies of slightly irregular outline.	Diplococci of large oval cocci.
5	4	400		Very small, very active bacilli, rounded or pointed ends, in twos and threes, not equally stained.
6	5	About 50,000	Mostly sm. round white colonies, greenish-yellow under microscope.	Plump bacilli, 1.65 m. long, in twos and threes, sluggish motion.

## BETHESDA (AERATED).

No.	hrs	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	6	87		
2	4	50	Mostly sarcina.	
3	5	80	Mostly sarcina, a few moulds.	
4	6	4	Irregular, not well-defined, superficial, colorless, transparent.	Bacilli, almost cocci, mostly in twos, sometimes three of varying shapes and sizes in one chain, some rounded ends, some pointed, some wide at one end and pointed at the other.
5	5	106	Small, circular, also a few sarcinae.	Bacilli 2-2½ m. long, ½ as wide, in twos and threes.
6	5	50	Solid, round, brownish.	
7	3	373	Brownish, coarsely granular, without sharp boundary.	Large bacilli, 3.35-3.75 m. long and 1.25 m. broad, single and in twos.
8	4	26		Sarcina.
9	4	43		Sarcina.
10	4	28		Sarcina.
11	5	23	Yellow, circular.	Bacilli with rounded ends, 2.5 m. long and half as broad, some not much longer than broad.
12	6	155	Liquefying.	Very mobile, short, diplobacilli.

## SILURIAN (AERATED).

No.	hrs	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	4	5		
2	4	28		Sarcina.
3	3	22		B. subtilis.
4	3	5		
5	5	507	Round, finely granular.	Bacilli.
6	3	34		

## SALUTARIS.

No.	hrs	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	3	267	Brownish-yellow, circular, granular.	Bacilli resembling b. subtilis in shape, size and motion, but not growing to such long filaments.
2	4	25		
3	4	21	Moulds and sarcinae.	
4	3	4	Sarcina.	
5	4	15	Sarcina and moulds.	
6	3	20	Sarcina and moulds.	B. subtilis.

## WHITE ROCK (AERATED).

No.	No. days growth.	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	4	33	10 per cent. moulds.	Sarcina . . . . .
2	4	114	Mostly very transparent, almost colorless, circular.	Majority sarcina . . . . .
3	4	10,678	Almost all large, circular, brownish colonies without well-marked border, but having short hairs projecting into surrounding gelatine.	Mobile bacilli, growing into long threads.
4	2	2,325		
5	3	15		Sarcina . . . . .
6	2	About 140	Much of gelatine liquefied.	

## MANITOU.

1	4	About 1,800	Liquid . . . . .	Bacilli .83 m. long and almost as thick; rounded ends, generally as diplococci, quite mobile.
2	5	74		Mostly sarcina lutea . . . . .
3	4	7		
4	3	About 2,500	1. Great majority sharply-contoured yellowish discs. 2. A number of double-contoured colonies with radiating lines.	Motionless bacilli, 1.66—2.35 m. long and .85 m. thick, with rounded ends, some not much longer than thick, single and in twos; very minute, active bacilli.
5	5	125	Small, circular, liquefying . . . . .	Short, plump bacilli, with rounded ends, in twos, rarely longer chains, also some threads, swim rapidly through field.
6	3	141	Yellow and brown, slowly liquefying.	Short, plump, diplo bacilli with rounded ends, centre often unstained, not very active.
7	5	10		Sarcina . . . . .
8	2	3,414		
9	2	17	Moulds . . . . .	
10	3	768	Solid colonies & moulds.	

## ROCKBRIDGE ALUM.

1	3	26		
2	4	26		
3	2½	88		
4	2½	19	Half moulds, half solid one liquid.	
5	5	18	Liquefying . . . . .	Many sarcina aurantiaca.
6	5	About 5,000		

## BLUE LICK.

1	4	488		
2	3	2,267	Elliptical, somewhat irregular.	Plump, somewhat mobile bacilli, in twos and threes, forming zoogloea.
3	4	4,088	About half as in 2; the other half similar colonies.	Same as 2; streptococci in chains of 2-8 links.
4	2	1,000	Many liquefying . . . . .	
5	3	1,767	Mostly small, white round colonies, greenish-yellow under microscope.	Plump bacilli, 1.66 m. long, in twos and threes, sluggish; also quite a number of sarcinae.

## COLFAX.

1	1	2,491		
2	3	141	Bacteria and moulds . . . . .	
3	3	2,200		
4	2		Principally granular, yellow to brown, circular discs.	Bacilli with rounded ends, mostly single, rarely in twos, never in longer chains.
5	4	100,000	Half sarcina, other half irregular brown solid colonies.	Bacilli, somewhat curved, about size of tubercle bacillus, with clubbed extremities, single and in short chains, extremely active, some shorter and thicker.
6	3	789	Brownish discs and irregular colonies.	Both kinds of colonies consist of short bacilli, not much longer than thick, generally in twos, so active that their shape can hardly be distinguished in hanging drop.

## BUFFALO LITHIA.

No.	No. days growth.	No. germs to 1 cm.	Character of Colonies.	Morphology of Micro-organism.
1	3	20		
2	2½	41		
3	2	142	75 per cent. are moulds . . . . .	Some sarcina and b. subtilis
4	2	21	25 per cent. are moulds . . . . .	Mostly sarcina . . . . .
5	4	61	Liquefying . . . . .	
6	3	312		Probably all sarcina . . . . .

## COLUMBIAN.

1	3	1,721	Solid, almost circular, well defined, somewhat darker in centre.	Bacilli slowly mobile, slightly curved, ends generally pointed, 1.66—3.35 m. long and .85 m. thick, in chains of two and three.
2	2	9,225	Same as 1, also same number of similar colonies . . . . .	Same as 1, very small, active bacilli almost cocci, in twos and also in chains of two and three, also some b. subtilis.
3	3	3,000		
4	2	2,700	About 1 per cent. b. subtilis, the others round and elliptical colonies . . . . .	
5	4	684	Solid, superficial, greenish-yellow, circular.	Bacilli in twos, 1.66 m. long and half as wide, slowly mobile . . . . .
6	4	441	Same as 5 . . . . .	Same as 5 . . . . .

## CASTALIAN.

1	3	8,136		
2	2	76,275	Bacteria . . . . .	
3	1½	30,150	Moulds and bacteria . . . . .	

## CRAB ORCHARD.

1	2	About 150,000	Solid . . . . .	Short shuttle-shaped bacilli, often in twos, but rarely in longer chains, often with an unstained spot in the center.
2	2	About 150,000	Majority are sharply defined, circular, granular, brownish colonies, also many large superficial, greenish, irregular colonies . . . . .	
3	2	About 250,000	Same as 2 . . . . .	Same as 2 . . . . .
4	2	About 150,000	1. Circular, finely granular colonies, darker in center than at edge, slowly liquefying. 2. Very light circular colonies, showing fine concentric lines. 3. Resembling pus corpuscles. 4. Resembling typhoid colonies . . . . .	1. Bacilli 1.05 m. long and half as thick, in twos. 2. Bacilli much finer than preceding. 3. Large bacilli of uniform size, 2.5 m. long and 1.2 m. thick, single and in twos, and also in threads of two or three . . . . .
5	2	About 100,000	First two varieties of 4 . . . . .	First two varieties of 4 . . . . .
6	2	About 100,000	Same as 5 . . . . .	Same as 5 . . . . .

## BETHESDA (Non-Aerated).

1	3	About 3,000	Liquefied . . . . .	
2	2	2,750	Great majority coarsely granular brown colonies, circular, with roughened outlines, many not bacilli.	Motionless threads, 2.5—6.5 m. long and ½ m. broad . . . . .
3	3	2,237	Root-shaped bacillus . . . . .	
4	4	2,400	Many of root bacillus . . . . .	
5	4	3,000	Root bacillus . . . . .	
6	3	8,644	Many colonies of root bacillus . . . . .	

SULPHOLEINIC ACID has been called "poly-solve" by Mr. H. Wilson, of Manchester. This product is produced by the action of sulphuric acid upon any kind of vegetable oil, and when concentrated is a yellow viscid liquid. It is capable of dissolving a large number of organic and inorganic substances, 2 per cent. of sulphur, 3 per cent. of iodoform, 25 per cent. of camphor, etc.—*Pharmaceutical Jour. of New South Wales*.

## THE MANAGEMENT OF LARGE HERNIE.

*Read in the Section of Surgery and Anatomy, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

BY J. COLLINS WARREN, M.D.,

OF BOSTON, MASS.

The interest at present felt by the surgical world in the radical cure of hernia is so great, and so many methods of treatment are being brought forward, that it has occurred to me that the grouping together of a number of examples of the extreme degree to which hernia may attain, and to relate my experience in their management, might not be without interest to the members of the Association.

The very large herniæ appear to have a *raison d'être* in each case; that is, the patient usually suffers from some form of disability which prevents him or her from exercising that control over a hernial tumor which an able-bodied and intelligent person is usually capable of doing. In a large number of cases obesity is a predisposing cause, especially in umbilical herniæ in women. A stout, middle-aged, swag-bellied woman who has borne children is particularly liable to this form of hernia. An examination of the abdominal parietes of such an individual will show a large semi-lunar fold running in a sort of festoon across the abdomen and containing at its centre a depression, marking the umbilicus. The size and weight of this fold of skin and adipose tissue must exert a strong traction upon the cicatricial tissues of the umbilicus, and the abdominal parietes at this spot must, therefore, be disposed to yield to pressure, especially if weakened by the distension of numerous pregnancies. In a laboring and ignorant woman a tumor once developed is not likely to grow any smaller, and soon becomes irreducible. If the intelligence of the patient is at all impaired, the conditions for the development of a large hernia become unusually favorable.

The type of man usually afflicted with a large scrotal hernia is two-fold. Either he is a middle-aged active business man, so engrossed with his work or of so careless a temperament as to have neglected his disease until driven to treatment by fear of permanent disability; or he is an old and feeble individual, or so obese as to be unable to manipulate the parts so as to effect a reduction, or with insufficient intelligence to apply and keep in place a truss.

Finally we have children with congenital hernia, whose position in the social scale is so lowly that the little patient has never been able to receive proper care, and an unusually aggravated form of hernia is the result.

The cases which I shall present to you for your consideration represents fairly well each of these types of this affection. No special plan of treatment has been adopted applicable to them all, but each case has received such treatment as the

special conditions governing it seemed to call for. Most of them have, however, had this in common, that a preliminary treatment was applied in all, consisting of pressure, with rest in the inverted position; that is, with the hips raised and the shoulders lowered. The object of this position is to reverse the conditions under which the gradual formation of the tumors occur; that is, pressure and gravity combine now to return the intestine and omentum to the abdominal cavity, as they had before combined to protrude them through the ring. The so-called inverted position is produced by raising the foot of the bed and so arranging pillows and mattresses as to make the ring the highest point of the abdominal parietes. Pressure can be made by sand or shot bags, or by the rubber band or special apparatus devised for the purpose. Usually, however, the position aided by sand bags so greatly reduces the size of the hernia that it can be reduced readily by taxis under ether. When it was not possible to retain the herniæ by any form of apparatus after considerable trial, the radical cure was then attempted.

*Case 1.*—*Large scrotal hernia, twenty-five years' standing.*—H. H. R.,<sup>1</sup> 45 years of age, had developed a small hernia during college life, but as it increased very slowly, had used no truss, nor had at first made any systematic attempt to reduce it. At the time I saw him he was exceedingly stout, his greatest weight reaching 340 pounds. The enormous size of the scrotum, a portrait of which, sketched by the patient himself, giving the exact size, I here show you, measuring 17 inches from the base to its most dependent portion, caused, after active exertion, the development of a troublesome eczema. After a hard week's work he would go to bed on Saturday and give the scrotum a chance to recuperate itself until Monday morning. Unsuccessful attempts at reduction had been made in Paris, London and New York, on at least one occasion under ether. On explaining the method of reduction by pressure to the patient, who was a skilled architect, he entered heartily into the plan and a bed was made of special strength and a frame work built around it by his carpenter, with an apparatus for hoisting the hips or body, as might be desired. The foot of the bed was raised, the scrotum was held vertically in a hard rubber splint made for the purpose, and pressure was exerted by shot and sand bags. A rubber bag that could be inflated rigid externally but flexible internally, and exerting a sort of uterine pressure, was made for this case by the Davidson Rubber Company. By the time this bag was ready for use the tumor had been reduced to one-quarter of its original size. The bag having been fitted over the hernia and held in place by bandages, pressure was exerted by water introduced into it, and, at the end of eight weeks, the hernia was reduced. The opening in

<sup>1</sup> Boston Medical and Surgical Journal, March 18, 1886.

the ring had a length of four finger breadths. The patient was not able to use a spring truss, but the hernia was retained with ease by a buckle and strap apparatus. The patient led a most active life after this, going up and down ladders and traveling great distances without any local trouble. He died about five years later of Bright's disease.

*Case 2.—Large scrotal hernia, twenty years' standing.*—This patient was about 40 years of age, the proprietor of a large factory, and an active business man. The tumor was about the size of an infant's head of six months and irreducible. It was chiefly omental, the amount of intestinal contents being small. A six weeks' rest in the recumbent position, with the foot of the bed raised and pressure with sand bags and occasional use of the rubber bandage, reduced the tumor so much that only one or two large nodules of omentum remained that could not be forced through the ring. Ether was accordingly given, and by vigorous manipulation the lumps were reduced. A truss fitted by Dr. Green, of Leach & Green, has held the hernia perfectly, and the patient has since, during a period of eighteen months, been actively engaged in business.

In neither of these cases did it seem advisable to attempt a radical cure. In case No. 1 the large size of the ring, its great depth below the surface, owing to the presence of large masses of fat, and the existence of Bright's disease, were sufficient grounds for not advising an operation. In case No. 2 suture of the rings might have been attempted, but unless I could guarantee a result which would make a truss unnecessary, it seemed to me preferable to try the treatment by reduction with subsequent use of the truss. This has proved so satisfactory that the question of operation has not been raised since.

The following cases show some of the difficulties to be met with in dealing with large umbilical herniæ:

*Case 3.—Umbilical hernia; reduction by taxis.*—Mary L., 43 years of age, entered the hospital on November 6, 1883. She is very stout, weighing over 200 pounds. A lump has existed at the navel for over ten years. It has increased in size, slowly diminishing at times, but never entirely disappearing. She has now a hernia the size of a small cocoanut, which emerges through an irregular opening apparently just below the umbilicus. Pressure by weight in the recumbent position entirely reduced the hernia, so that a truss could be fitted which held the hernia comfortably.

*Case 4.—Large umbilical hernia; operation for radical cure.*—Mrs. Rice, 45 years of age, mother of a family and a very large and stout woman, noticed a bunch about the size of a marble protruding from the navel. This gradually increased to the size of a fist, but could be put back. For the last five years the tumor has been irreducible

and has increased considerably in bulk, and the patient has suffered from frequent attacks of abdominal pain, nausea and constipation. On examination a hernia the size of a child's head (8 inches in diameter) was seen bulging from a broad abdominal fold. It was tympanitic and evidently consisted chiefly of intestine. By rest in bed with the foot raised for a month and pressure with sand bags the tumor gradually grew smaller, and finally was reduced by taxis, without ether, through an opening admitting three fingers. The patient was sent home to try the value of a truss. Three months later she entered the hospital for radical cure, as no truss or support could hold the hernia.

Case 4.—Before operation

A median excision about six inches long laid open the sac. There were numerous bands and adherent masses of omentum, between and around which protruded the intestines. The appendix was adherent to the right wall of the sac and also a portion of the colon. These were dissected off, the bands were divided and portions of the omen-

tum removed. The edges of the ring were brought together with six silk buried sutures, and the opening in the sac was then closed with superficial silk sutures, a small portion of it having been excised. The wound healed by first intention, with the exception of a small tube sinus, which closed at the end of two months. The patient remained in the hospital one month and then returned and kept her bed one month longer. At the end of three months she showed herself and a photograph was taken. A hard, indurated mass covers in and closes the site of the old hernia. There is no expulsive motion in coughing, and the cure appears to be complete. She has worn no retentive apparatus.

CASE 4. Six months after operation

Twelve months after the operation she was sent for and reported that she had been in perfect health and actively at work—never better for many years; had used no apparatus. A slight return of the hernia was found, of the existence of which the patient was unaware. Since that time has worn an abdominal belt, which prevents the hernia from increasing in size.

*Case 5. —Large umbilical hernia; operation for radical cure.* L. S., 60 years old, married, young-

est child 25 years old; stout and unwieldy; mental standard not a high one. Entered hospital with an umbilical hernia considerably larger than a child's head. First noticed a rupture at the umbilicus thirty-five years ago, after jumping from a carriage. On examining herself, found a tumor about the size of a fist. Used at times a truss and a swathe. Five or six years ago it began to be very painful, and during the past year has increased rapidly in size. It has never been reduced. Has a history of epileptiform seizures at night. The circumference of the abdomen at umbilicus is 42 inches. The hernial tumor is lax and soft when patient is lying down, and the skin over it at points exceedingly thin. It measures 13 $\frac{1}{2}$  x 14 inches. After a week's rest in bed with sand bags over tumor the patient was etherized, and after three quarters of an hour's taxis the whole mass was reduced through the ring, which was large enough to admit four fingers. The ring was padded and supported with a large adhesive plaster swathe. During the next two weeks the hernia was controlled by bandages, but it was evident that no truss would hold it, and the patient was accordingly etherized again and the sac laid open. In the interior the bowels were found nested in a large number of pouches. A considerable portion of the ascending colon, with the vermiform appendix, was found pointing in front, with a large portion of small intestines behind it. The appendix was so adherent that it had to be excised, in order to reduce the colon and its appendages so that they would remain without tension within the abdominal cavity. Many bands were divided and fragments of omentum excised. The edges of the ring were then brought together and sutured with six coarse silk sutures. The integuments were then brought together with silk sutures and two drainage tubes inserted. The wound healed apparently by first intention, and there was but slight pyrexia. There was considerable mental disturbance following etherization, and the patient tried to get out of bed the first night. This condition, however, soon passed away, and the wound had apparently healed when an abscess formed in one of the mucous pouches. This was opened, but the fistula has not yet healed, six months since the operation. The patient is about with a large pad over the umbilicus, at which a tumor about one-quarter of the original size presents. An examination shows that the stitches in the ring have yielded.

*Case 6. —Double congenital hernia; MacEwen's operation.* Chas. Green, 11 years old, small of stature and below average intelligence, entered the hospital April 28, 1888. Six years before had been advised by me to wear a truss, which had been used from time to time with slight success. The photograph gives an inadequate idea of the hernial tumor, which reached one-third of

the distance to the knees when fully distended. The rings were so large that the first finger and thumb of one hand could be introduced into the rings and made to meet easily in the abdominal cavity when the hernia had been reduced. On May 1st the right hernia was operated upon by MacEwen's method for congenital hernia, *i. e.* a portion of the sac was left behind to form the tunica vaginalis. The wound was closed with a continuous catgut suture and healed by first intention. Three weeks later the other side was operated upon in the same manner. A small sinus remained for a few weeks, which had healed by July 1st. Was discharged without a truss August 1st. On his removal from the convalescent ward he had a urethral calculus and retention of urine at his home, which put the cicatrix to a severe strain, but he went through the ordeal successfully. Examined by me nine months after the operation, a slight return of both herniæ had occurred as the result of falling down the cellar stairs backwards. He still wears no truss, but the hernial tumors are small and do not trouble him. His family having removed to Providence, I have been unable to see him a second time.

*Case 7.—Large scrotal hernia in an old man.*—The photograph of this case, which I show you, gives a type of a certain class of cases of hernia, easily reducible, but which have been allowed to grow to an enormous size owing to the mentally or physically feeble condition of the patient. The present case is an Italian who does a certain amount of work, but is unwilling to buy a cheap apparatus or put himself permanently under treatment. The hernia is quickly reduced by the patient by catching it between the thighs, which give diffused pressure, when reduction is finally effected by the hands. For this class of cases I am in the habit of advising a large suspensory bandage made of jean cloth, which effectually prevents increase in size, reduces considerably the size of the hernia, and gives the patient a comfortable sense of support. The large size of the ring renders strangulation extremely improbable. These herniæ sometimes are subject to attacks of local peritonitis, but the use of the support is a good prophylactic against this accident.

*Case 8.—Large incarcerated hernia reduced by Dr. Warren's method, by C. W. Galloupe, M.D., Harv. 1883, of Lynn, Mass.*—My patient is a large-boned, heavy man, 46 years of age. At the age of 17, while in the act of lifting a cask weighing 825 pounds into the rear end of a wagon, his foot slipped a little on the snow, and he felt a sudden stinging pain in the left groin. This pain continued, and at the end of a week or ten days he noticed a swelling in the groin as large as the end of a thimble. He kept constantly at work, however, until at the end of two years his father noticed that he seemed weak and disin-

clined to lift. He then explained the cause of his laziness, and at that time examination disclosed a bunch the size of a hen's egg.

An iron truss was applied by a country practitioner, which was discarded the next day on account of the pain it caused. In five years from the date of injury it had dropped down into the bag, and he was then fitted to a knitted bag, which acted as a suspensory. The rupture had increased constantly but slowly up to a year ago, when it was about the size of a cocoanut. At that time he jumped from a horse-car and felt a sudden yielding, while the rupture doubled in size in an hour's time. Since then it has steadily increased and has prevented him from doing any active work. There has been but little pain, but a constant pull and drag that has made him an invalid and has led him to indulge freely in alcoholic stimulation.

At the time I first saw him, March 28, 1889, the hernia measured 25 $\frac{1}{2}$  inches in circumference around its base, 30 inches around its largest part, and its length from pubes to center of perineum was 17 inches. It was of the left inguinal variety, but on account of its size, and the fact that it had dissected up the skin from the lower part of the abdomen and from the upper part of the thigh, the ring could not be felt nor the contents mapped out. He was placed supine on a hard bed with the foot elevated 10 inches, the bowels evacuated and the diet restricted to concentrated and digestible foods. At the end of forty-eight hours the œdema of the scrotum had subsided sufficiently to disclose the nature of the contents of the sac. The upper portion contained many coils of gut, while the lower part and the part next the ring were solid and nodular. Efforts at reduction were made and a considerable part of the gut returned. A cotton bandage was then applied in circular turns to form a pedicle to the mass, and three sand bags, of 3 and 5 pounds weight, laid on the top, while a broad sling over the shoulders and around the neck held the mass vertical. On the fifth day the intestine could be all reduced, and the mass measured 21 inches in circumference by 14 in length. The residue was omental, the chief obstacle being a hard, solid cake 4 inches in diameter and 2 inches thick. The ring could be felt easily, admitting three fingers. From the outset the cotton bandage was applied once or twice daily, and after a few days a rubber bandage outside the cotton. No attempt was made to exert pressure by bandaging across the top, as the effect of this was to gradually squeeze the mass out under the ring of bandage and cause the whole apparatus to slip off. For the same reason the sand bags were of but little value, the chief reliance being placed upon daily manipulation to break up the omental lumps and dilate the ring, while the tight circular bandage caused an internal tension which constantly tend-

ed to squeeze out the contents of the sac. No pain was felt at any time unless the rubber bandage was too tight. If applied directly to the skin it would roll up and cut in uncomfortably, so that the following plan was adopted: Ten yards of cotton bandage, 2 inches wide, were wound around close to the abdomen, including the penis and testicles, each turn being wound still closer, so as to form a hard constricting collar about 4 inches wide; outside of this was wound the rubber, being worn about three hours at a time.

On April 14th, the seventeenth day of treatment, while squeezing the omental cake, it seemed to separate on one edge and open out to form a crescentic mass, which was insinuated by its smaller end into the ring and by dint of steady pressure was wholly reduced, exposing an opening through the abdominal wall which easily admitted four fingers. A graduated compress and spica bandage retained the hernia, and two days later the patient was up and around the room with a water-pad truss on. Much difficulty has been found in getting a truss which would retain the omental lumps, but no intestine has escaped since the first reduction. The patient is attending to his daily work and has gained considerable fat since he got up, while the scrotum has shriveled very greatly and the ring has closed up about one-half.

An incarcerated hernia of this size was not a very promising case to undertake, more especially as it had proved itself unyielding to many physicians during the past twenty or thirty years; but having had the satisfaction of tending a number of such cases under Dr. J. Collins Warren, in the Massachusetts General Hospital and in private practice, I was encouraged to try it by his method of treatment. The result shows the value of his method, and the freedom from pain and danger will make the patient readily consent to it.

I regret to say that I have not yet succeeded in effecting a radical cure in any of these cases; but I may add that all the patients have been fully satisfied with the result of their treatment. I would recommend strongly the method of gradual reduction by pressure to the members of the Section. I do not advance it as a new method, for it is in reality exceedingly old, but I don't think physicians generally realize how much can be accomplished by it.

In the large umbilical hernia the failure to get a permanent cure is due, I think, to the neglect to excise the edges of the ring before suturing. In order, however, to bring the different layers of the abdominal walls together, as in a laparotomy, the amount of dissection necessary would have greatly prolonged the operation and might have increased the danger. On another occasion, however, I think I should attempt it even in as complicated cases as these were.

## ADVANCEMENT OF THE TREATMENT OF INSANITY DURING THE NINETEENTH CENTURY.

*With Notes upon the History of the Treatment of the Insane in Louisiana, up to the Close of the Year 1859.*

BY JOSEPH JONES, M.D.,

PROFESSOR OF CHEMISTRY AND CLINICAL MEDICINE, TULANE UNIVERSITY OF LOUISIANA, ETC., NEW ORLEANS, LA.

### THE ADVANCEMENT IN THE TREATMENT OF THE INSANE DURING THE NINETEENTH CENTURY.

Dr. Benjamin Ward Richardson, of London,<sup>1</sup> in a recent article, entitled, "Medicine Under Queen Victoria," dated July 25, 1887, has clearly shown by indisputable facts, that this first great advancement in the science of medicine commenced *practically* in the year when Queen Victoria ascended the throne half a century before, and consisted in the *adoption of the method of treating the insane without violent physical restraint.*

What the practice of medicine in the treatment of the insane had been previous to 1837, it is in this day almost impossible to conceive.

Dr. Benjamin Ward Richardson says:

"There was in it no science and certainly no humanity. I remember perfectly as a youth, climbing the wall of a barn in order to look through a small grated window at a poor lunatic, who for twenty-five years had been chained in one corner of the place, and in that condition had been retained and kept by his relatives as a dog, or other savage animal might have been. He was bedded down in straw just as other animals were, and except that it was put for him on a platter his food was given to him as might have been given to a dog. He took his food in his hands and tore it with his teeth, the idea being that it was not safe to let him have a knife or a fork, or anything more than a wooden spoon as a help for feeding. The people who had this man in charge were not more cruel than the rest of mankind. They labored under the idea that it was for the safety of themselves, and on the whole for the benefit of the insane man that he should be kept as he was kept. Had he been set at large he would have done some mischievous or dangerous thing for which he would have been punished, and for which they would have been responsible. It is true, they might have sent him to a madhouse, but there he certainly would not have been better cared for than at home. He would have been under the rod of strangers, and might have been exhibited as a show to those

<sup>1</sup>The Asclepiad: "A book of original researches and observations in the science, art and literature of medicine, preventive and curable." By Benjamin Ward Richardson, M.D., F.R.S. Third quarter, 1887, page 267. Longmans, Green & Co., Paternoster Row, London; J. Blakiston, Son & Co., Philadelphia, U. S. A.; Cupples, Upham & Co., Boston, U. S. A.

who were curious for strange sights. He might also have been irregularly fed or imperfectly clothed to meet the various seasons. As it was he was kept out of mischief; he did not complain, he gave little trouble, and he was not merely safe himself, but was a safeguard to the lonely home or lodge attached to the barn in which he was domiciled. For strangely enough the poor helpless creature was a terror to the superstitiously wicked, to the prowling vagrant, the thief, the burglar, and the incendiary. When he cried or howled or laughed maniacally, the wicked were alarmed into flight. The notion in those days was also common that the insane at particular times were under the influence of the moon; that lunacy was a lunar problem was indeed a belief as absolute as that the moon itself appeared monthly in definite quarters, and that she governed the tides. This belief is not effaced yet, but so strong was it at the period of which I was speaking—the latter part of the last reign—that the brother of the lunatic, to whom reference was made above, would make his calculations as to the states of mind into which the lunatic would pass by reckonings of the moon, and sometimes it really seemed as if his predictions were correctly cast.

"As an illustration of the barbarities which were practiced in these institutions, my late friend, the distinguished George Cruikshank, gave me this engraving, which he etched in his time from an original drawing by G. Arnald, F. R. A., of a man named William Norris, an insane American, who was riveted alive in iron, and was for many years confined in that state by chains twelve inches long to an upright massive bar, in a cell in Bethlehem Hospital.

"I have no personal recollection of the state of asylums at the first period of the present reign, but I have heard from others much that excites the surprise of the present generation when it is told. The asylums were conducted on the worst and cruellest of systems. All government, if such it may be called, was by force and fear. The insane were looked upon as endowed with superhuman strength and craft, as human machines of great power, cunning and viciousness, uncontrolled by reason or any attribute of common sense. It was but therefore, to keep them at all times under restraint, and to make in some cases the form of restraint unchangeable, permanent and irresistible.

The system of pinioning the insane in so decisive a manner as Norris was pinioned, was probably exceptional, but pinioning in a milder manner was the rule rather than the exception. Manacles attached to the limbs and secured by chains to the bunks or beds in which the insane slept were in common use, and what was called the straight waistcoat by which the upper limbs were kept under bandage, was so universal that

it remains by name a word of reproach towards the violent until the present hour. 'He ought to be put in a straight waistcoat,' is still a frequent vulgar declaration.

"The centrifugal and the centripetal treatment on a wheel were other methods followed out for the management of the insane up to the latter part of the period preceding the Victorian. It had been ingeniously surmised that the amount of blood supplied to the brain could be increased or lessened by placing a living human body on a horizontal plane attached at a right angle to the axis on a large revolving wheel. If the head of the sufferer were placed on the circumference of the wheels, then it was assumed that the blood in the body would be forced into the brain as the wheel went swiftly round. If on the contrary, the sufferer were placed with the head to the centre and the feet to the circumference, the brain would be emptied of blood as the wheel revolved. One of the medical friends of my early days saw this machine in motion, and made inquiries as to the effect it produced. His record in respect to it was, that if the prayers of the sufferers not to be put upon it, their screams on it, and their giddiness and sickness when they came off it, were to be accepted as signs of improvement, then the treatment might be considered to have been of value; but that he could trace out no instance whatever in which any insane person had been cured by the experiment.

"The Rev. Dr. P., is a very learned man, who, in my first days of practice, was a patient under my care, told me that in a great asylum of which he was at one time a governor, the attendants were detected in the act of dressing the insane under a system of the most astonishing kind, called by them 'the long stocking quietner.' When a patient was to be dressed in the morning, the attendant went to the bed or bunk of the victim, passed round his neck a long, soft stocking, and gently, but firmly, twisted the stocking until the throat was sufficiently compressed to produce a temporary asphyxia and insensibility. Then another attendant came, and while this rough anæsthesia was sustained, dressed the semi-suffocated body for the day. The plan on being exposed, was not without its defenders, who urged that the process gave no pain, that it was attended with no bad results, that it saved hours of possible suffering, and that it was humane, because it did away with all necessity of chastisement, with stripes and struggles, and with injuries to the dressers as well as to the dressed.

"These various modes of government of the insane were not confined to those of the insane who were poor, and, if it be fair to use the term, friendless. The rich were shut up in separate houses, large or small, and were subjected to the caprice which the unwatched powerful, almost of

necessity extend to the unprotected weak. Even royalty itself did not escape. From the moment when the unfortunate George III betrayed his insanity in his speech at the opening of parliament: 'My Lords and gentlemen, and woodcocks cocking up your tails,' he shared with his subjects the servitude of the insane. There are some pictures of him extant, showing him during the period of his insanity, which are simply appalling in the misery they exhibit. They are pictures of fear concentrated and abiding, as well as of a mind weakened and feeble. The story so often repeated, that the king while in confinement at Windsor, was chastised into obedience, was largely credited, and was excused as a necessary part of the treatment of the insane. The exhibition of the king by his keepers for gain was not considered at all a detestable measure, and that he received hard usage is, I fear, but too true. While visiting a large asylum in 1860, the proprietors brought to me a man of advanced life, who had been engaged in his zenith as a younger or assistant keeper of the poor king during the pitiful and painful Windsor period, and this man told us that he himself had seen his majesty knocked down for his obstinacy.

"Such is the background of the picture of insanity and its treatment previous to the present reign. I should rather say it is a portion of the background only, for to fill it up entirely would indeed be a task impossible.

"For some time previous to the Victorian era there had been a few good and humane efforts to relieve the insane of a certain amount of the oppression to which they were subjected. Their names in connection with this effort deserves special mention: Pinel, of the Bicetre, in Paris, the Elder Luke, in the retreat of York, and Dr. Charlesworth, in the city of Lincoln, Lunatic Hospital, in which institution the grand final and triumphant experiment of entire freedom of the insane was carried out." (*The Asclepiad*, 3d Quarter, 1887, pp. 207-209.) Dr. Benjamin Ward Richardson concludes his valuable observations on, "The First Advancement, The Treatment of the Insane," in the following words:

"There is nothing more striking in the course of medical science than the improvement of the insane by the abolition of restraint. It may be considered as a complete conversion, extending throughout all our wide confine. It has planted us first among all nations as physicians of mental disease, and has yielded the best literature on insanity that has ever been produced.

"Strangest fact of all, we have obtained, as an outcome of the system of treatment under the love that casteth out fear, a literature of the insane by the insane, edited, printed I believe, and published by the inmates of the Morningside Asylum in Edinburgh, is one representative of the literature which alone would suffice to illustrate

the success of the instalment of practical medicine in the history of the people living under the sceptre of Victoria." (*The Asclepiad*, 3d Quarter, 1887, p. 214.)

#### TREATMENT OF INSANE IN LOUISIANA.

Much has been accomplished in the alleviation of the condition of the insane of Louisiana, but much remains to be accomplished, and many abuses, such as those which we have described in the preceding pages, remain to be rectified. We will give no fancy sketches, but will present authentic facts as revealed in official reports, which we have obtained after much careful research.

#### TREATMENT OF THE INSANE IN NEW ORLEANS, LOUISIANA.

New Orleans was founded about one hundred and seventy-one years ago, but what was the fate of the unfortunate insane during the dominion of France and Spain, and during the early occupation of the United States in the early part of the nineteenth century must remain in doubt and obscurity.

After a careful search we find no authentic records of the early French and Spanish Hospital in New Orleans; they appear to have been removed together with other archives to the respective foreign governments. The following facts are of importance in the light which they throw upon the history of the Charity Hospital of New Orleans, and will serve to aid us in ascertaining as far as possible the material available for the preparation of a history of human efforts towards the proper treatment of the insane in this city.

The Charity Hospital, of New Orleans, commenced its career as a private hospital and continued so from 1779 to 1811, when it was given to the city of New Orleans. In 1830 it became a State institution, and has remained so ever since.

From 1830 to 1840 it was supported by a tax derived from licensed gaming-houses, which was ample for the purpose. In 1846 to 1847, the legislature levied a tax of \$2.50 a head on all immigrants from foreign countries landing from vessels at the port of New Orleans. This income was large, and continued for several years, but it gradually diminished from \$76,000 collected in 1854 to \$14,000 in 1859. It was in consequence of the diminished revenue derived from foreign immigrants, that the Charity Hospital became more and more a burden to the State treasury. It is evident from the preceding facts that the city records of the Charity Hospital date from 1811 and the State records from 1830.

It is evident that the Charity Hospital of New Orleans was occasionally charged with the care of the indigent insane, for we find that in 1843 the number of cases, entered upon the hospital records as due to insanity, was forty-eight with five deaths, twenty-three discharges and twenty

remaining. In 1832 mania is credited with twenty-one cases and seven deaths; melancholia, two cases; monomania, three cases. The records of the hospital are not at this time accessible to the writer—between the years 1833 and 1842—but we have reason to believe that the insane of the city received at different times assistance, either directly or indirectly, through the administrators of the Charity Hospital. In such reports as I have been able to examine, between the years 1832 and 1849, the destructive effects of alcoholic stimulants are well marked. Thus in 1832, thirty-two cases of delirium tremens were entered, with thirteen deaths, seventy-nine cases of intemperance with fifteen deaths. In 1842, mania a potu, 122 cases and twenty-nine deaths, inebriety, forty-six cases, three deaths; 1843, mania a potu, 51 cases, five deaths. In 1846, delirium tremens, 159 cases, twenty-five deaths; mania a potu, sixteen cases. In 1848 delirium tremens 177 cases, fifteen deaths; inebriety fifty-two cases, five deaths, mania a potu eight cases, fifty-nine deaths; intemperance, eighty-four cases; mania a potu, ten cases.

After careful examination of the archives of the Charity Hospital of New Orleans, with the kind assistance of Sister Superior Philomena and Sister Agnes, the following facts were established:

1. The wooden building on the right of the main building on Common street was devoted to the treatment of the indigent insane of New Orleans up to the time of their removal to Jackson in 1848.

2. The lower rooms were used as cells for the violent patients. The third story of this wooden building (now known as the female department on Locust street) was occupied as sleeping apartments by the attendants of the insane.

3. The iron bars remained on the windows of this wooden (Locust street) building of the hospital until 1872, when Sister Agnes had them removed.

4. The insane department of the Charity Hospital was in full operation in 1846, and was visited and inspected in this year by Sister Philomena, on her way to Natchez, Mississippi.

5. It is probable that the report of the division for the insane was for a portion of the time, at least, rendered separately from that of the hospital generally.

I have sought information from all available sources amongst those who have resided in New Orleans during a considerable portion of the present century, and was rewarded by the following communication from Judge Charles Gayarré, the venerable and learned historian of Louisiana:

"NEW ORLEANS, May 8, 1889.

"PROF. JOSEPH JONES, M.D., 156 Washington Ave.,  
 "My Dear Sir:—I have understood that before the existence of the insane asylum at Jackson, demented persons, who, before 1848, were not numerous, used to be taken care of at home by their own families, when

this could be done. Otherwise, these unfortunate beings were sent to the Charity Hospital, where, if I am not greatly in error, there was a part of the building appropriated for them. I regret to say this is all I know on the subject.

"I gladly avail myself of this opportunity to renew to you the expression of my high esteem and distinguished consideration.

Very truly yours,

CHARLES GAYARRÉ."

The preceding statement of Judge Gayarré corresponds to all the facts that I have been able to collect with reference to the disposition of the indigent insane in New Orleans prior to the year 1848.

#### TREATMENT OF THE INDIGENT INSANE IN NEW ORLEANS, LA.

The Legislature of Louisiana in March, 1847, passed "An Act to Establish an Insane Asylum in the State of Louisiana." The asylum was first thrown open for the reception of patients in December, 1848. Previous to this time a portion of the indigent insane were cared for by the Administrator of the Charity Hospital of New Orleans. Upon their arrest the indigent insane were first incarcerated in a building attached to the Parish Prison consisting of a series of ill-ventilated cells, and this continued to be the custom up to the use of the United States Marine-Hospital building as a city insane asylum.

#### TEMPORARY ASYLUM FOR THE INDIGENT INSANE OF NEW ORLEANS IN 1856.

*Notes furnished by Dr. C. Delére, City Physician, upon the Temporary Insane Asylum in New Orleans.*—"When Dr. Delére entered upon his duties, December 1, 1856, the asylum contained fifty-six persons; one of them had been there for a year, others for several months. The insane were huddled together in the cells, and they often fought each other at night, and some came forth in the morning with their heads barbarously bruised with the blows they had received.

"Dr. Delére has addressed some petitions to the Common Council to inform them of the abuses which reigned in the asylum. Upon the entry of his duties a lunatic was compelled to undergo a detention of sixty days before he could be conveyed to Jackson. Upon Dr. Delére's demand the Council, some three or four weeks since, adopted a resolution authorizing the City Physician to demand, whenever he should judge proper, the conveyance to the asylum at Jackson of every lunatic sent to the temporary asylum, without the delay which heretofore they have been compelled to undergo at the said temporary asylum.

"The City Physician complains that lunatics, beggars and persons afflicted with delirium tremens, are all sent, without distinction, to the temporary asylum. He deems it a violation of the laws of humanity thus to confound two classes of persons separated by the abyss of insanity.

"He deems it of the highest importance to expedite as much as possible the conveyance to the Jackson asylum of the insane sent to the temporary asylum, for the hygienic condition of the temporary asylum is entirely unsuitable to the treatment of insanity, whilst the same hygienic conditions at Jackson offer the same advantages; besides, that this last establishment is perfectly prepared for the treatment of this sad affliction.

"The City Physician further thinks that there should be another asylum similar to the one at Jackson, near the city, and for the following reasons:

"1. Since most of the insane are furnished by the city, the proximity of the place will enable the relations to visit them easily and more frequently.

"2. The expense will be much diminished, since the transportation of the insane from the city to Jackson is very expensive.

"3. It will be a source of emulation to the physician at the Jackson asylum, who, instead of being isolated as now and abandoned to his own solitary exertions, will find himself surrounded by *confères*, with whom he would be enabled to exchange the lights of experience.

"In the present state of things an individual, upon being sent to the *temporary asylum*, is submitted to the examination of the physician of the establishment (the City Physician), who retains him until he has obtained accurate information of his mental condition. He is sent in virtue of an order of a recorder, which order is issued upon the affidavit of any one. If the individual is attacked with delirium tremens only, the doctor retains him and only restores him to liberty when he has perfectly recovered his senses. If he finds that the individual is afflicted with mental alienation, he fills up one of the blanks furnished by the City Attorney, and sends it to the Judge of the First District Court. The Judge then fixes a day for the examination of those designated as insane. The City Physician is summoned, is put upon his oath, and swears that his affidavit (contained in the above mentioned blank form) is true. After this the Judge orders the sheriff to have the insane (who has thus passed through the form of the law) sent to the asylum at Jackson."

Dr. Barkdull, physician of the Insane Asylum at Jackson, wrote in 1857 on this subject:

"The opinion I have formed respecting this prison has not been derived from anybody, or friends of patients, but from a more reliable source than either of these, namely: from the filthy condition in which we receive those who have been confined there any length of time."

156 Washington Ave., New Orleans, La., Aug. 19, 1889.

## THE CLINIC.

### GYNECOLOGICAL CLINIC.

BY E. E. MONTGOMERY, A.M., M.D.,

PROFESSOR OF GYNECOLOGY IN THE MEDICO-CHIRURGICAL HOSPITAL OF PHILADELPHIA, AND PRESIDENT OF THE SOCIETY OF AMERICAN GYNECOLOGISTS AND OBSTETRICIANS.

[Reported for THE JOURNAL.]

*Carcinoma Uteri.*—Mrs. G., æt. 35 years, married, mother of four children, eldest æt. 19, youngest 9 years, no miscarriages. Labors were normal. She has enjoyed excellent health, until within the last two years when she first noticed that her menstruation recurred every three weeks, beyond which she experienced no especial discomfort until last March, when she had a continuous bloody discharge. She then consulted a physician, who found a laceration of the cervix covered with exuberant granulations which he several times curetted preparatory to an operation. She improved for a short time when the condition became more severe than ever, menses were very free and continued for eight days. Within the last two months severe pain began to occur, and was quite severe and lancinating. The character of the symptoms from which she complains taken with the physical signs to be described later, leads us irrevocably to the diagnosis of malignant disease.

Malignant disease occurs with greater frequency in the uterus than in any other organ. In the uterus, the cervix is most usually the seat of origin. This greater relative frequency goes far to confirm the assertion that it originates as the result of some previous injury. The cervix is the natural site of injury during the processes of parturition. This is still more evident, when we consider the infrequency of carcinoma in the uterus of the unmarried female. The disease is most likely to occur between the fortieth and fiftieth years of age, but, in my experience, in the wards of the Philadelphia Hospital, I have seen a number of cases in women between 20 and 40. In these younger cases, the disease seems to have an especial virulence, and is much more rapid in its progress. The period of greatest frequency is that near the climacteric. A patient in good health will notice that her menstrual flow becomes excessive; that it is followed by a thin watery discharge, often quite irritating and having an unpleasant odor, or the menses may have ceased for months or years, and there is a slight return of bloody discharge following coition or some unusual exercise, or the discharge may be quite profuse and the woman thinks she is having a return of the menses. The patient may suffer from severe lancinating pain, or this symptom may be entirely absent. I cannot too strongly impress upon you, the importance of excessive menstruation, or hæmorrhage, at or near the menopause.

THE JOURNAL will be sent to any address from now until January 1, 1891, for \$5.00.

Permit no patient suffering from this symptom to be in doubt as to the possible gravity of her situation, and insist upon the importance of physical examination to determine its cause. Not unfrequently the anxiety produced by such symptoms are lulled with the assurance that it is indicative of change of life and will cease with the menopause. This is a false security and consumes valuable time. Under such a delusion the opportunity for medical relief escapes, and patient and physician awake to find a fatal termination confronting them. Examination of this patient discloses a large spongy mass filling up the vagina; passing the finger about it, nodules are felt upon the vaginal walls and upon all sides. The uterus is quite large, more or less fixed, and indications of involvement of the broad ligaments. As we look at the patient we see a peculiar anæmic appearance, occurs often as combined result of the hæmorrhage discharge, pain and mental distress.

The cachexia is accepted as an indication of systemic infection. It is doubtless due to the absorption of material from multiple abscesses in the degenerated tissues, as the removal of the latter is often followed by a healthy appearance of the skin. The extent of the disease in this woman precludes the possibility of a radical cure. Where the disease is confined to the uterus, however slight, whether confined to the cervix or the body, the only justifiable operation, in my opinion, is the extirpation of the entire organ. Just as we would remove a whole mammary gland, when one of its lobules was diseased, so would I believe the subsequent immunity against relapse greater in carcinoma uteri when the whole organ has been sacrificed.

This operation, however, is only justifiable, when the disease is confined to the uterus, the presence of vaginal involvement, infiltration of the broad ligaments, nodules in the intra-uterine peritoneum, or tissues, would preclude it for the reason that it is not justifiable to subject our patient to a grave operation that affords no hope of a successful result. But the time for the radical cure having gone by for this patient, is there nothing we can do that will afford her an opportunity for prolonged life, for increased comfort?

The patient is now suffering from hæmorrhage, from the drain of a continuous discharge, and from the absorption of septic material. The relief of these symptoms for a time will improve her condition and prolong her life. This we will endeavor to accomplish by scraping, curetting and cutting away the diseased tissue until firm solid tissue is reached. We place the patient in the semiprone position and insert a Sims' speculum. As I do so, you see this brain-like appearing mass, filling up the vagina. I proceed to scrape this away, using my finger as the safest curette for the reason that I am better able to judge by it the extent of the disease, the amount

of involvement of surrounding parts, and avoid the possibility of opening into an adjoining viscus.

Having completed the removal so far as is possible with the finger, and ascertained that we can safely use the curette. I now use this sharp curette which has, as you see, a hole through its handle, and from this fountain syringe we will keep a current of water playing upon the parts as the curetting is done. By so doing the detritus is continually washed away, and we have the influence of heat, or an antiseptic, upon the denuded surface. With the scissors we now cut away the ragged edges, and I show you the uterus with a funnel-shaped cavity excavated nearly to the fundus. There is considerable oozing from this surface, to control this, and prepare the parts for the next step we apply some pledgets of absorbent cotton saturated with liq. ferri persulph. 1 to water 3, making a firm tampon in the vagina. This tampon will be left 24 to 48 hours and removed, the vagina carefully cleansed and protected by sodii carbonas. 5j, vaseline 5j, and pledgets squeezed dry from zinci chlor. and aq. aa, 5j, applied to the raw surfaces. In the application of this agent, it is extremely important to protect well the vaginal surfaces. The sodii bicarbonas. unguent, is an excellent agent for this purpose. It should be spread over the surface of the vagina and about the vulva. The uterus is exposed by the Sims' speculum and the pledgets applied so as to come in contact with the diseased surface; dry cotton is applied over it and then a large pledget wet with a saturated solution sodii bicarbonas. This agent neutralizes the superfluous caustic and prevents the destruction of the vaginal and vulvar tissues. These applications are removed in twenty-four hours and the vagina syringed several times daily. The slough begins to separate about the third day, and is completely thrown off in from a week to ten days. The extent of the slough will depend upon the amount of the organ involved and the excavation of its cavity. The method of treatment is often followed by most excellent results. The general appearance becomes much improved, the face bright and healthy, the hæmorrhage arrested, the discharge ceases, and pain is lessened. The return of the disease in its active form may be delayed by a suitable regimen and the administration of certain remedies. The diet should promote the nutrition and enrich the blood, as beef, mutton, eggs and milk, in other words an albuminous diet. Of remedies, arsenic, mercury and chian turpentine are most highly appreciated. While I have not had the marked results from the use of the turpentine claimed for it by its special advocate Mr. Clayet, I have seen several cases in which the progress of the disease seemed much less rapid under its use.

## MEDICAL PROGRESS.

A COMPARISON OF ANTIPYRETICS.—From a comparison of cases, in which he has carefully tabulated the effects produced, DR. A. CROMBIE, of Calcutta, has reached the following conclusions:

1. As regards efficacy, antipyrin comes first, and there is little to choose between antifebrin and phenacetin.

2. Regarding safety, the advantage lies with phenacetin.

3. As regards rapidity of action, antipyrin, probably on account of its solubility, comes first, antifebrin second, phenacetin third. The fall of temperature after the use of phenacetin is more gradual, and the minimum is not reached for three, four, or even five hours after the administration of the drug.

4. As regards duration of effect, the advantage lies with phenacetin.

5. As regards certainty of action, the order is the same as that of rapidity, *i. e.*, antipyrin, antifebrin, phenacetin.

6. As regards inconveniences in a hot climate, like that of India, phenacetin is followed by just as profuse sweating as that produced by either antifebrin or antipyrin, and this is the great drawback in the use of antipyretics.

Dr. Crombie believes that there are often cases of fever following chill or exposure to the sun when the exhibition of antipyretics is promptly followed by a cessation of all further febrile symptoms. In remittent and continued fevers antipyretics exert no specific action and are, upon the whole, inferior to the cold pack, although there are often practical difficulties in the way of using the pack which render the administration of antipyretics imperative. Hyperpyrexia in itself is inimical to life both by reason of the structural changes which are induced by it, and the disturbances of digestion which occur when the temperature exceeds  $103^{\circ}$ . Phenacetin excels the other antipyretics in possessing a soothing soporific effect. In heat, apoplexy, sunstroke and hyperpyrexia generally, antipyrin is indicated; in temperatures of  $103^{\circ}$  to  $105^{\circ}$ , antifebrin or phenacetin; in temperatures below  $103^{\circ}$ , preference should be given to phenacetin.—*Indian Med Gaz.*, July, 1889.

A CASE OF EXTRAORDINARY ELEVATION OF TEMPERATURE.—DR. LORENTZEN (*Cent. für Klin. Med.*, August 17, 1889) reports the case of a married woman, 20 years of age, where the bodily temperature reached the remarkable height of  $112.8^{\circ}$ . The patient was under treatment for hæmoptysis, but exhibited no other signs of phthisis. She had numerous attacks of dyspnoea, in some of which she became cyanosed and lost consciousness. The attacks were accompanied

by severe pain in the left side on a line with the anterior margin of the axilla, in the fourth intercostal space. There was also a moderate degree of hyperæsthesia in the left ovarian region. There was no cough and no hæmoptysis during the attacks. The attacks themselves generally followed emotional excitement. There were occasional periods of sudden retention of urine, requiring the use of the catheter, but there were no other manifestations of hysteria. On the 9th of January, 1889, when the patient had been under treatment for several months, the reporter found his patient in a feeble condition with eyes closed, face flushed and skin dry, but not very warm. She was slightly delirious and complained of pain in left side and back and of nausea. Dr. Lorentzen measured the temperature in the rectum, allowing the thermometer eight minutes in which to register, when the mercury was found to measure  $112.8^{\circ}$ . The rectal temperature was again measured, this time with a second thermometer, while the axillary temperature was taken with a third, the results being respectively  $112.8^{\circ}$  and  $112.6^{\circ}$ . The pulse at this time was 144, respirations 24. The thermometric measurements were taken with great care and with corrected thermometers. The temperature remained high for several days, after which it dropped to normal. The patient recovered gradually and remains well at date (July, 1889). In default of a more satisfactory explanation the reporter ascribes the elevation of temperature to hysteria.

COMPRESSION OF PULMONARY ARTERY IN THE COURSE OF ACUTE PNEUMONIA.—DR. E. TORDIET (*Journal de Médecine*, No. 14) records the case of a child, 5 years of age, admitted into hospital for well-marked acute lobar pneumonia of the left upper lobe, who presented a loud systolic murmur in the second left interspace, and traceable toward the axilla. The bruit persisted when the patient was discharged, but so also did the dulness and bronchial breathing at the left apex. The notion of congenital narrowing of the pulmonary artery was unsupported by any collateral evidence, and it was shown that similar bruits have been described which were subsequently proved to have been due to pressure upon the pulmonary artery by enlarged glands or plithisical consolidation. It was therefore surmised that a like causation explained the bruit in this case—a notion which was borne out by the fact that the bruit completely disappeared later, when a soft hæmic apex murmur alone was audible.—*The Lancet*.

ANTISEPTIC PROPERTIES IN HUMAN SALIVA.—From a series of experiments with the saliva of human adults, DR. FLORADIN has found that the sulpho cyanide of potash, which is always present, has decided antiseptic properties.—*Prager med. Wochenschrift*, Aug. 21, 1889.

SATURDAY, NOVEMBER 16, 1889.

## STATE EXAMINATIONS AND SCHOOLS OF MEDICINE.

There can be little difference of opinion regarding the need for a higher and more uniform criterion of professional attainments than now exists, and few observant men, outside of medical college faculties, will deny the absurdity of allowing possibly incompetent teachers to examine and license the pupils whom they may have faultily or insufficiently instructed. But the search for a practicable method of reform must encounter many difficulties, general or local, inherent in our system of government. In countries where imperial control is exercised over medical education, the prescription of the subjects and sequence of the curriculum, the constant supervision of teaching, and the selection of the fittest to conduct the final examination, are theoretically feasible, and may be made to extend throughout the domain. In America, it is doubtful if national regulations could be legally established, even if there were agreement concerning their desirability, and the chance of improvement must depend on the separate action of geographically continuous, but constitutionally severed States, of whose legislative bodies it is hardly derogatory to say that they are rarely guided by a profound knowledge of the scientific bases of the *ars medendi*, but are usually rather actuated by the hallucination that the sole purpose of the entire faculty of a medical school is to impart to successive classes of unreasoning pupils certain traditional and inflexible dogmata touching the

administration of drugs. At the prompting of this curious misconception, charters have been granted to "homœopathic" and "eclectic" medical colleges; in some instances even wilder therapeutic vagaries have been incorporated with collegiate powers; and as an inevitable result, several schemes for State examinations in medicine have been defeated by the clamor of these one-idea "schools" for equal representation in the examining boards. In New York, which has been one of the greatest sinners in the matter of indiscriminate charters—exerting a severe nominal quarantine against physicians from other States or foreign parts, but leaving it open for any of its own irregular chartered schools to countersign the diplomas of Paris, London, Berlin, or Podunk—a recent convention of the homœopathic fraternity naively resolved that the creation of a State board composed chiefly of "allopathic" examiners would probably lead to the obliteration of homœopathic doctrines, and that a fund should be raised to influence legislators against the passage of any Act tending toward such a disastrous end. With "practical politics" as sponsor for the offspring of the morganatic alliance between ignorance and law-making, and the "new code" faction officiating as monthly nurse, the rachitic probability of short life does not prevent the cries of the fretful twins from disturbing the peace of the neighborhood; and harassed governors, as well as the perturbed public, may be tempted to administer some "soothing syrup" for the sake of their own quiet. And until the public, including law-makers and governors, shall have learned that there is as great a difference between a medical school and a "school of practice" as there is between a horse-chestnut and a chestnut horse, and that it is worse than folly to attach the adjective, "homœopathic" or "eclectic," to anatomy, physiology, pathology, and the other sciences which constitute a medical education, the one subsidiary chair of materia medica will continue to absorb exclusive attention, and to present a rock whereon all argument will split.

If this mischief making subject, as usually taught, were abolished from all our schools, the sacrifice would be small in comparison with the advantage gained. We say, "as usually taught," for when we smile at the gibberish of the Hahnemannian "symptomen codex," with its "Acon.

Ars., Bell., Bry.,” and so on to the end of the alphabet, we must remember that in our own ranks there are routinists from whom students learn little or nothing of the toxic or physiological action of drugs, but only the empirical statement that quinine is “good” for paroxysmal fever, or that a combination of rhubarb and soda is appropriate in childhood, with a series of arbitrary prescriptions for the names of different diseases. The miscalled chair of “Practice of Medicine” has been modified by the advance of scientific knowledge, until it means to-day the principles of medicine, and its occupant concerns himself much more with pathology and diagnosis than with medicinal treatment, dealing, as the scientific mind must ever deal, with facts rather than with opinions. If the dry bones of “materia medica”—covered only with the mummified integument of imaginary and antiquated “therapeutics”—were laid at rest in a hermetically sealed sarcophagus, and its place ceded to a living pharmacology, teaching the “how” and “why” of toxic or remedial action, the graduate would be enabled to intelligently adapt his treatment to the pathological indications of the case before him, and the squabbling of sects would soon cease. None save unblushing charlatans would venture to object to an examination which should test the candidate’s knowledge of general and special pathology and the demonstrable facts of pharmacology, leaving to his own judgment and conscience the practical correlation of the knowledge so displayed; and no prophetic gift is needed to foresee that the requirement of such knowledge would lead to the extinction of “schools” founded solely for the maintenance of visionary theories.

#### DREAMS.

We have somewhere seen a story of a young mother who, seeing her baby smiling in its sleep, exclaimed: “The little darling! The cherubs are talking to it.” “Oh, no mum,” replied the nurse, “’tain’t the cherubs—it’s the colic!” It is to be feared that the progress of science has tended, for the time, to detract from the poetical feeling with which dreams were regarded when they were supposed to be supernatural warnings, portentous of the fate of individuals and of nations. Still, although we may no longer hope to

learn the way to fame and fortune while sleeping off a Christmas dinner, and even the divination of one’s future partner for life by dreaming over wedding cake sometimes fails, the mental phenomena of sleep are by no means unworthy of study, not only for their intrinsic interest, but on account of their affinity to the various morbid psychical states.

In the *American Journal of Psychology*, Vol. I, No. 3, MR. JULIUS NELSON gives some of the results of observations made upon himself as a preliminary to the study of the general subject of hallucinations. He says that he possesses the dreamy diathesis in an extraordinary degree, which would certainly seem to be borne out by his statement that he has memoranda of over one thousand dreams per year for the period of more than three years covered by his observations. A prophylactic measure, which he found efficacious against bad dreams in childhood, is curious enough to be quoted: “On composing myself for sleep, the object of a dreaded dream was by voluntary act brought before my mind, and while held there I said mentally, ‘Shall I dream of that?’ (here visualizing the scene which past dreams had taught me to fear) and then the subject was dismissed with a confidence that I should not be troubled by that dream for that night.”

He finds that his dreams may be divided into three distinct classes: The first, which he calls “evening dreams,” are only experienced on going to bed in a tired and sleepy condition, without becoming fully awake in the process of undressing. In such circumstances the transition from a semi-conscious state to one of normal repose is marked by a sudden nervous discharge, accompanied by a spasmodic start, which often coincides with the tragic climax of a dream. In the second class, “night dreams,” the mind continues to be busied with the ideas and emotions which have engrossed the attention during the day. The third, and by far the most numerous class, “morning dreams,” occur after the brain has been refreshed by the night’s repose, and “differ from the foregoing classes in the fact that they are new or varied combinations of past mental experience, worked up with great fertility of fancy and multiplicity of transformation.”

In compiling his observations he found that the variations in the amount of dreaming on different nights were not altogether irregular, but

presented a certain rhythm, the period of which was twenty-eight days. He also found that sexual excitement, as shown by the frequency of nocturnal emissions, presented a corresponding, though not altogether coincident, periodicity. He is inclined to bring the two facts into relation. A question like this, however, can hardly be decided by observations on a single subject.

HEERWAGEN, in "Philosophische Studien," Vol. V., No. 6, undertakes the investigation of dreaming by the statistical method. He obtained answers to 406 circulars on the following points: Sex, occupation, frequency, vividness and distinctness of recollection of dreams, duration and soundness of sleep, time of day at which intellectual work is most easily performed, nervous troubles, and temperament. Of the persons furnishing the information 264 were men, of whom 151 were students, and 142 were women. The following are his principal conclusions: Women sleep much less soundly than men, and dream much more. Dreams are more frequent in light than in sound sleep. With advancing age, however, while sleep becomes less sound, dreams diminish in frequency. Dreams are more vivid and better remembered in persons who dream frequently. With men, dreaming seems to have no influence on the need of sleep, but women who dream frequently sleep nearly half an hour longer than those who dream seldom. As might be anticipated from the foregoing, those who dream much go to sleep less quickly and are less likely to have unbroken rest than those who dream little. Of the students, 80 per cent. sleep through the night without waking; of the other men, 70 per cent.; of the women, only 43 per cent. Intellectual labor is easier in the morning to those who sleep soundly and dream little. Nervousness is favorable to dreaming, and is more frequent in women. Persons of phlegmatic temperament sleep most soundly and dream least. The author supposes that the reason of the inverse proportion of the frequency of dreams to the soundness of sleep is due to a greater sensitiveness of the brain to internal as to external stimuli.

It is not probable that the subject is by any means exhausted, and the material for further researches is available to almost anyone. It is to be hoped that scientific researches in this field will be less rare in the future than they have been in the past.

## EDITORIAL NOTES.

## HOME.

LI PO TAI, a Chinese physician, who has resided in San Francisco for thirty years, is said to have a professional income of \$6,000 per month.

THE TRANSPORTATION OF DEAD BODIES.—The Association of Baggage-men, which recently met in Detroit, passed resolutions insisting that all bodies of persons dead from contagious diseases, held for transportation, must be properly prepared for shipment by being wrapped in sheets saturated with mercuric chloride and placed in metallic caskets, to prevent the spread of the disease.

THE COUNTRY DOCTOR is the title of a new journalistic venture to be issued January 1, 1890, under the editorial management of Dr. J. T. McColgan, of Arcot, Tenn.

TO OUR READERS.—Through a mistake in our mailing department duplicate copies of THE JOURNAL of November 9 were sent to some of the members and subscribers. We shall esteem it a favor if those receiving said duplicates will return them *at once*, addressed to the Business Department, 68 Wabash Ave., Chicago, Ill. Write on the outside wrapper from whom returned, and the postage (two cents) will be remitted to the sender.

THE MEDICAL MIRROR.—This is the name of a new monthly medical journal to be published in St. Louis, Mo., the first number of which will be issued in January, 1890. It is to be edited by Dr. I. N. Love, who is already so prominently connected with medical journals that he needs no introduction either to the editors or readers of our prominent periodicals. His name in connection with the *Mirror* is an ample guarantee that its reflections will be at once clear and truthful, and that it will shine by inherent rather than by borrowed light. It will not busy itself about "that long felt want," but will create wants for itself, and in its manner of dealing with these its readers will doubtless find abundant satisfaction. We bespeak for the *Mirror* a generous support on the part of the profession, confident that it will be an honor to medical journalism.

DR. JOHN S. BILLINGS, of Washington, D. C., will deliver the Cartwright Lectures this year. The subject will be "Vital and Medical Statistics."

A NEW MEDICAL COLLEGE BUILDING.—Work has been commenced on a new building for the Medical College of the New York Infirmary for Women and Children, at the corner of Livingston place and Fifteenth street.

DR. H. LONGSTREET TAYLOR succeeds Dr. A. B. Thrasher as Editor of the *Cincinnati Medical Journal*.

NORTH CENTRAL ILLINOIS MEDICAL ASSOCIATION will hold its sixteenth annual meeting in the Congregational Church, LaSalle, Ill., on Tuesday, December 3, commencing at 10:30 A.M. The annual public address will be delivered in the evening by Dr. Henry Ziesing, of Peru, on "Heredity and Adaptability as Factors in Education." This Association embraces several counties and nearly one hundred members. Its meetings of one day and evening only are replete with matters of interest to the general practitioner; its discussions practical and free, and the relations of its members cordial and unreserved. Physicians eligible to membership are invited to unite therewith and contribute papers or clinical reports and present for examination rare and interesting cases of disease or pathological specimens. The Secretary is Dr. Wm. O. Ensign, of Rutland, Ill.

THE HUDSON RIVER STATE HOSPITAL at Poughkeepsie, N. Y., is to be enlarged.

#### FOREIGN.

SANITARY COUNCIL IN TEHERAN.—The last number of the *Weekly Abstract of Sanitary Reports* issued by the Surgeon-General of the U. S. Marine-Hospital Service, contains the transactions of the Sanitary Council held in Teheran on September 10, and submitted by Dr. W. W. Torrence to E. Spencer Pratt, United States Minister.

It is reported that four Jews, natives of Bagdad, having avoided quarantine, have arrived at Kermansha. They are closely confined and have been forbidden to go about.

Various information received from Khanakin regarding cholera, is reported to have been without foundation and unofficial. Some objection being raised by the European physicians as to the reliability of this report, it was suggested that the Persian consul resident at Khanakin should be the proper informant.

The Turkish physician asked as to state of inhabitants of the country lying between Kerse-ih-

Shirun and Khanakin; that they should be led to hope that something definite was being done for their relief; that it is necessary that four physicians be stationed each at Kerse-ih-Shirun and Kermanshah, two to be engaged attending patients with cholera, and the other two to attend those suffering from other disorders, and perhaps one other to be engaged in superintending quarantine regulations.

A question having been asked by a European physician as to the measures being taken to remove bad odors, his excellency the Nasier el Malk, president of the council, replied that full regulations had been instituted formally for the carrying out of all that is necessary in that respect in quarantine.

The physicians said, in reply, that strict regulations were necessary, and must be carried out wherever cholera exists; that most particular pains should be taken as regards cleanliness and removal of bad odors, the thorough cleansing of houses and thorough fumigation, and that those dying of cholera should be wrapped in cloths dipped in a proper solution of perchloride of mercury. His excellency, the president, replied that as regards cleanliness and fumigation, such orders have and will continue to be given, but that as regards burial and corpses, nothing could be done contrary to the religion and custom of the country.

According to latest reports from Khanakin cholera has increased, and at Bundakauh and on the other side of the river also; that it is very severe in the tribe of Jof and on the increase, many dying daily; that the people are scattered.

In Khanakin, on the 17th of Moharum, six persons died of cholera, on the 18th five. Apparently the disease is milder, but it is reported that the Gaiam-Migom has forbidden any one reporting the number of deaths.

A MEDICAL SERVICE for the Chinese army and navy is to be established.

A NEW OPHTHALMOLOGICAL SOCIETY has recently been established in Paris under the presidency of M. Chevalereau.

THE RIFORMA MEDICA, the Neapolitan daily medical journal, has received the first prize in the Section of Medical Publications at the Exhibition of Hygiene and Medicine, recently held at Padua, Italy.

## TOPICS OF THE WEEK.

## ANCIENT SURGERY IN GERMANY.

Ambroise Paré, who became a master barber-surgeon in 1536, and died in 1590, has been called the reformer of surgery, and the French claim in particular that their illustrious countryman was the first to apply the ligature to arteries. PROFESSOR EDMUND ROSE, in an address delivered before the "Freien Vereinigung Berliner Chirurgen" May 13 of this year,<sup>1</sup> laid before the meeting a copy of a work dated 1497, by Jeronymus Brunschwyg, a Strassburg surgeon. On page 19 of this work is a colored woodcut of an operation room, with a description of various instruments then in use—the amputating knife and saw, various probes, needles in handles, small hooks for taking up arteries ("damit aufzuheben die Adern"), small and large spatulae, bent to assist in drawing out the ligature ("die do Haar uss ziehen"), etc. Further on the whole *armamentarium* for the extraction of shots or pellets is given. It must be remembered that the arquebuss, the first form of gun fired by a trigger, first came into use about the middle of the fifteenth century. On page 51 are represented six simple trephining instruments.

Professor Rose is troubled because, even in the latest edition of a well-read German surgical work, Paré is still called "the reformer of surgery," whereas his surgery was still "barbaric" when other surgeons had made advances. His oxen with human heads are exactly the same as in Licetus. He was not the first to abandon the old way of treating gunshot wounds (namely, by pouring boiling oil into them), nor did he discover the ligature of arteries, or bring it into general use. Petit, himself a Frenchman, protested against this prevalent idea in the eighteenth century, and at the close of that century Mursinna, in Berlin, commended his way of controlling hemorrhage after removal of the mammary gland. A plug with a complicated dressing was fastened over each separate artery. Jeronymus Brunschwyg's own words run thus: "*Dass ist, so du siehest ein Ader fast pluten, als an dem Hals die Glessader (carotid) oder ein verwundete Pulsader, dass du die Ader heranziehst mit der Nadel und dadurch stichest, und inter Nadeln die Ader verknuffest mit dem Faden, der do in der Nadeln ist, und dann der Nadeln durchziehst. Und ein Stucklein Fadens an der Ader bleibt hengen, uber etlich Tag verfaulet das ober Theil des Adern, und geht der Faden heraus.*" [That is, when you see an artery bleeding fast, such as the carotid in the neck, or a wounded "pulse-artery," you draw out the artery with the needle, and thereby penetrate, and tie the artery behind the needle with the thread which is in the needle, and then draw out the needle, and a small piece of thread is left hanging from the artery. After some days the upper end of the artery mortifies (decomposes), and the thread is detached.] These words are plain enough; the man who used them had evidently ligatured arteries himself.

As regards gunshot wounds, old Jeronymus Brunschwyg acted on the sound principle of extreme cleanliness. He spoke of poisoned arrows, etc., just as we, a few years

ago, talked of "infected" wounds without any clear idea of wound diseases. He cleansed the wound with violet or linseed oil (occasionally camphorated), and expressly says "*ein wenig gewarmt*" (a little warmed). Thus, he did not advocate the use of boiling oil in such cases. Long afterwards Ambroise Paré omitted the use of this latter means of treating gunshot wounds on one occasion, and tells us that he could not sleep that night from anxiety for his patient's welfare. As to washing with goat's milk, this had already been recommended by Heinrich von Pfolsprundt in his *Buch der Wundth-Ertzei*, published in 1460. The above fluids were evidently found to be antiseptic, or rather free from noxious germs of their own, hence their proved utility on many a battle ground.

The unguentum olei has been called the balsam of Arcaeus. We find the same balsam in Brunschwyg's work. Here it is spoken of as "that best of all balsams for recent wounds that can be had, and its like can hardly be found." And again, "it almost makes flesh grow." But, in another place, he inveighs against the indiscriminate use of that "Strassburg balsam, discovered about the year 1460, and now spread abroad throughout all Germany."

Refracture after faulty union of fractured ends of bones has been attributed to a Swabian surgeon of the name of Bosch, who lived in the middle of the last century. This also is bosh. Brunschwyg did the same thing; he either broke the bone across his knee or laid the limb, enveloped in a cloth, across two supports, and trod on it with his naked foot. Extension was effected gradually by screws; that is, in recent cases—old ones were let alone, on the principle, as we are told, that it is "better to be alive and limp, than to die even with a straight limb."

"Window" bandages were recommended for compound fractures and wounds. A "doldrunk" was given sometimes to overpower a patient with sleep, so that incisions might be made and a fragment of an arrow, etc., removed without pain. The chief ingredient was opium. Ancient surgery in Germany, to judge of this work, had evidently arrived at a high pitch before Ambroise Paré was born.—*Editorial—British Medical Journal.*

## THE HIGH DEATH-RATE IN RUSSIA.

DR. LEINENBERG, of Odessa, publishes in the *Internationale Klinische Rundschau* a lengthy article on the mortality of Russia, which is full of interest for the statistician. He says that in the number of births alone Russia ranks first of all European States, as they annually amount to no less than 48.8 per 1,000 of the population. The latter would consequently grow with abnormal rapidity if an enormous mortality did not make this impossible. This mortality is, according to Janson, 37.3 per 1,000, while the Statistical Central Committee reports it at 36.8 per 1,000. As to the causes of such high figures, Dr. Leinenberg points out that they depend largely on high infantile mortality. He states that 104.8 boys are born to every 100 girls, and that amongst the Jews the proportion of boys born rises to 128.9 for each 100 girls. The mortality of boys, as of the male sex in general, is correspondingly greater than that of the female sex, in the proportion of 36.7 to 35.2. Of 1,000 newly born chil-

<sup>1</sup>Berliner Klin. Wochenschrift, July 1, 1889.

dren 263.4 die before they are a year old. This mortality in the first year of infancy is in the province of Novgorod 281 per 1,000, and in the Rusk district of the province of Moscow it reaches the figure of 550.8 per 1,000. Even this enormous number has been surpassed by the town of Irbit, which shows a mortality during the first year of life of 560.2 per 1,000. The provinces of Ekaterinoslaw and Wilno are distinguished by the lowest infantile mortality, the figures mentioned in the report of the Statistical Central Committee being 139.7 per 1,000 for Ekaterinoslaw and 118.9 per 1,000 for Wilno. Comparing the infantile with the general mortality in Russia, the author points to the following two important statistical results: Children up to the fifth year of age form more than one-half of the deaths from all causes. Infantile mortality shows a tendency to increase every year. This great infantile mortality in Russia must be largely attributed to the want of proper diet and of sufficient care, especially amongst the agricultural population. In summer, which is the time when nearly all the children die in the country, the parents are in the fields, leaving their infants at home with no supervision and without sufficient food. This sometimes leads to strange and sad accidents, as in a case mentioned by Giljarowsky, in which pigs devoured the buttocks of a child which had been left alone at home for a considerable period. Griassnoff attended a child which under similar circumstances had been attacked by goats and had lost every finger on both hands. Dr. Leinenberg also goes on to speak of the health of those who have passed the crisis of the fifth year. Of 1,568,315 boys born in the year 1858, only 750,622 were alive in 1879, and when out of this number 272,974 were examined for the purpose of military conscription, 58,824 men—i. e. 21.5 per cent.—were found to be suffering from various incurable or chronic diseases, and had consequently to be returned as unfit for military service; so that of all boys born in 1858, 47.8 per cent. reached their twenty-first year, but only 37.6 per cent. preserved good health. —*The Lancet*.

#### FIFTY YEARS OF COUNTRY PRACTICE.

DR. ALONZO GARCELON, ex-Governor of Maine, is 76 years old, and is still in the active practice of his profession. He this year completes the semi-centennial of his medical career. The *Lewiston Journal* gives us some gossip regarding the doctor's life-work, but particularly about his travels. He estimates that with his horse and chaise he has driven about three hundred and sixty-thousand miles, or fourteen times around the earth. Such an estimate is based on the supposition that he has travelled an average of a little less than twenty miles a day, or seven thousand two hundred miles a year.

This is perhaps, a rather high estimate, but it is quite within the bounds of possibility.

The reflection which occurs to one in contemplating these figures is that an enormous amount of purely mechanical and unproductive labor has to be expended by the country doctor in his daily work. While this time is not by any means all lost, for there is health and mental rest, or, perhaps, productive ratiocination, in a moderate amount of ambulation, yet three thousand miles is too

far for the average man to go with horse and carriage, and expect to do the highest class of work in life.

It is all the more credit to Dr. Garcelon that he has succeeded in travelling pretty nearly as far as to the moon and back, and yet has acquired both political distinction and medical prominence. But the country practitioner most needs a means of locomotion swifter than the horse. Dr. Garcelon in riding his three hundred and sixty-thousand miles has had to give up nearly seven solid years, and twenty years of working days out of his total fifty, simply in riding to his patients and home again.—*Medical Record*.

#### RESPONSIBILITY OF THE DRUNKARD.

M. MOTEL read a paper on this subject before the International Congress of Psychology recently held at Paris. He said that a man was not responsible for a crime committed during the delirious period of drunkenness, nor when the crime was committed by a man suffering from chronic alcoholism, whose brain has undergone those changes which compromise the regular functions of the organ. The responsibility was attenuated in the cases of those persons naturally of a weak intellect and who take drink badly; it is also extenuated when it has been proved that the man got drunk unintentionally. On the contrary to those who got drunk with intention, and where alcohol was taken to give courage in order to commit a crime, no extenuation should be allowed. In conclusion, the author proposed that in presence of the great increase of alcoholism in France, and the terrible crimes committed under its influence, the government be invited to take steps to guarantee society against criminal dipsomaniacs, and for that purpose to establish special asylums for the treatment of habitual drunkards. The assembly adopted this proposition unanimously.—*Medical Press and Circular*.

#### THE FRENCH SURGICAL CONGRESS.

The fourth French Surgical Congress was opened on October 7, in the grand amphitheatre of the Faculty of Medicine of Paris, under the presidency of M. Larrey, who succeeded M. Vernenil. About one hundred surgeons, members of the Congress, were present. The President delivered a short address, after which the Secretary-general, Dr. Pozzi, read a list of the names of the officers of the Congress. Among the names of the Honorary Presidents occurs that of Sir Thomas Longmore, of Netley. Several papers were subsequently read. On Tuesday the time of the Congress was chiefly occupied by a well-sustained discussion on the immediate and remote results of operations performed for local tuberculous affections. During the sitting on this day, a fire broke out in the great amphitheatre, and the members had to make a speedy exit. The pictures, tapestries, and hangings, as well as the seats and tables, were burned, and the amphitheatre had a narrow escape from destruction. The fire is said to have been due to the overheating of the *calorifère*. Some of the paintings destroyed represented episodes in the history of medical science, and were very valuable. The damage is estimated at 30,000 francs.

## PRACTICAL NOTES.

### THE EFFECTS OF THE PROLONGED USE OF ARSENIC.

The effects of the continued use of arsenic have been the subject of so much discussion of late in connection with the Maybrick case, and so many statements have been made by those whom we are unable to recognize as able to speak with authority, that the following expression of opinion from Mr. Jonathan Hutchinson, which we take from the second instalment of his *Archives of Surgery*, will be read by all with interest. He writes: "My experience in its medicinal use has been very considerable, and my impressions as regards its effects when long continued are certainly very different from what we have recently seen so freely expressed. I never knew a patient become fond of arsenic, or experience agreeable effects from its long continuance. On the contrary, nothing but anxiety to be rid of a loathsome skin disease will induce the majority of those for whom it is prescribed to continue taking it. Its general effect if pushed is not to give vigor, but to diminish it, and make the patient feel apathetic and uncomfortable."—*British Medical Journal*.

### SULPHONAL.

M. Raymond has recently tested, at the St. Antoine Hospital, the value of sulphonal as a narcotic. Though far from being an ideal narcotic, it proved useful in many cases. It had scarcely any action on the respiratory system; on the circulatory system it had the same influence as sleep when this was natural; the temperature was slightly lowered. The secretion of urine was increased, that of the sweat glands diminished. The tongue and mouth were sometimes dry; occasionally, though rarely, the patient vomited. M. Raymond found that sulphonal was not an anæsthetic; it had sometimes a hyperæsthetic action. Small doses had no influence on muscular contractility; doses of 6 grams were followed by ataxic movements of the limbs. Doses of 1 or 2 grains were safe; women were more easily affected by sulphonal than men. Progressively increasing doses were unnecessary. After a certain time it could be discontinued; sulphonal was superior to morphine in this respect. It was especially useful in insomnia resulting from general debility, neurasthenia and cerebral disturbance; where there was actual cerebral lesion the action of sulphonal was more intense, and in such cases it had to be administered with great care. Sleeplessness from abuse of morphine was relieved by sulphonal; it was also useful in phthisical patients who were rendered sleepless by coughing. It was inert when sleeplessness resulted from rheumatic pains, sciatica, cardiac troubles, also

in Bright's disease and intense dyspnoea. Sleep produced by sulphonal was calm, lasted from six to eight hours, and came on about half an hour or one hour after administration. The disadvantages attending the use of sulphonal were fatigue, giddiness, and sometimes positive vertigo.—*Paris Correspondence British Medical Journal*.

### THE COCAINE HABIT.

DR. E. FLETCHER INGALS writes us a note regarding the cocaine habit as follows:

I have just read the article in the *Journal* by Dr. Morgan, on Cocainism, and although much interested in the report of the case, I feel confident that the doctor's conclusion, viz.: "In the treatment, the drug should be immediately and totally discontinued," and his further conclusion that the habit is harder to conquer than any other, are radically wrong.

I have had much experience with cocaine, and have had two cases in which the habit ruined the individual, but in either of these cases, I believe, it would have been an easy matter to withdraw the drug gradually and finally entirely, if they could have been properly cared for. In both of them the drug was gradually reduced without their knowledge, until at last 75 per cent. had been cut off, and this without hardly exciting the suspicion of the patient. If at that point they could have been taken in charge by some authorized friend, the habit could have been easily stopped without distress to the patient. These cases came from my early use of the drug, when I gave the patients a prescription for it, and cautioned them not to use too much. I have learned that it is never safe to prescribe cocaine, for although the habit may under proper conditions, I think, be easily broken, it is more easily formed than the opium, alcoholic or chloroform habit.—*Indiana Medical Journal*.

### IS PHENACETIN A REMEDY IN WHOOPING COUGH?

DR. R. HEIMANN, of Landau, answers the above question affirmatively, having used the drug experimentally in a case in which antipyrin entirely failed. The success was so surprising that he administered the drug in two other cases. It reduced the number of paroxysms, which had been from ten to fifteen per diem, to three, and on some days they entirely ceased, only reappearing at night, when no phenacetin was given. Dr. Heimann gave a boy of 3 years 6 grains in four doses of  $1\frac{1}{2}$  grains, a girl of 2 years 5 grains in three doses, and an infant of 7 months 3 grains in four doses, without observing the slightest ill effects. One grain and a half of phenacetin would, on the average, retain its effect for three hours. The author recommends further trials of the drug.—*Lancet*.

## SOCIETY PROCEEDINGS.

## Tri-State Medical Association.

*First Annual Meeting, held at Chattanooga, Tenn.,  
October 15 and 16, 1889.*

In pursuance to a call issued by several Societies of Alabama, Tennessee and Georgia, delegates from these States met in Chattanooga and effected the permanent organization of what promises to be an excellent Association.

## FIRST DAY.

The professional part of the proceedings began with *Microscopical Demonstrations* by Dr. Jas. E. Reeves.

DR. W. L. GAHAGAN read a paper on *The Physiology of the Heart and its Valves*.

The paper contained an accurate description of the muscular anatomy, the innervation, the action and the sounds, normal and pathological, of the heart.

DR. DRAKE said that the question "What makes the heart beat?" had not yet been satisfactorily answered, and called attention to the importance of recognizing the differences in the nervous mechanism of the lower and higher orders of animals.

DR. JAMES E. REEVES read a paper entitled *The Importance of the Microscope in the Practice of Medicine*.

Remarks on the paper were made by Drs. W. C. Townes, G. A. Baxter and J. B. Cowan, who all emphasized the importance of microscopical investigations at the bedside. The paper was carefully written and the subject handled in so masterly a manner as to be above criticism.

DR. J. E. PURDON, of Cullman, Ala., reported  
A CASE OF FRACTURE OF THE SKULL IN AN OLD  
MAN—RECOVERY.

The man was 65 years old, and the interest in the case lay in the fact of recovery at that age from such an extensive fracture. The opening, after the removal of bone, was 3 inches or more. The fracture was over the third convolution. The loss of memory of names was a marked symptom from which the patient had only partially recovered.

The discussion, participated in by Drs. G. A. Baxter, E. T. Camp, W. L. Gahagan, James E. Reeves, J. F. Lynch, J. B. Cowan, P. B. Green, W. B. Wells, Jas. Grange and Frank Trester Smith, was largely on the location of different centres of the brain and the effect and symptomatology when injured, and the use of the trephine.

DR. BAXTER related a case in which there was an anomalous distribution of the anterior branch of the middle meningeal artery, which was wounded while trephining for compression caused by a

blood clot. The hæmorrhage was controlled by pressure, the plug of bone having been inserted in the opening. Later the blood clot broke down and was discharged. There was good union of the plug of bone and full recovery.

DR. ANDREW BOYD, of Scottsboro, Ala., read a paper on

## CROUPOUS PNEUMONIA,

in which he briefly reviewed and discussed the etiology at length, holding the view that the disease is due to a specific germ, citing cases to prove his position. He thinks the diagnosis can only be made from physical signs, and that the rusty sputum and herpes labialis are pathognomonic. The disease runs a definite course from seven to fourteen days. He mentions four varieties of treatment: depletory, sedative, stimulating and mercurial; and reasoning from analogy he concludes that the best plan is to keep down the fever and stimulate the heart.

The paper was discussed by Drs. G. W. Drake, Jas. E. Reeves, P. D. Sims, E. T. Camp, J. E. Purdon, C. N. Cooper and J. B. Cowan.

DR. DRAKE called attention to the importance of keeping in mind the difference between fibroid phthisis as sequelæ and croupous pneumonia.

DR. MAX THORNER, of Cincinnati, presented a paper entitled

## IMAGINARY FOREIGN BODIES IN THE THROAT.

These were divided into three classes: 1. Cases where something had been removed from the throat but the sensation of a foreign body remained; 2. Cases where the sensation was due to some pathological lesion of the throat; 3. Cases where neither of the above causes exist but where the sensation is either reflex or produced by some remote ailment; as, for instance, indigestion, or where the trouble is purely neurotic. The treatment varies. Some can be persuaded that there is no foreign body there, in some it is necessary to resort to innocent deception. The author cited a case. Pathological conditions, as enlarged tonsils or uvula, varicose veins on the back of the tongue, hypertrophied papillæ or lymphoid nodules on the tongue, should be removed. Inter-current affections should be treated. Cases of a purely neurotic character are rarely permanently relieved.

The paper was discussed by Drs. N. C. Steele, Frank Trester Smith and N. C. Cooper.

DR. SMITH related a case where deception had been unsuccessfully tried, and called attention to the importance of a careful examination for pathological conditions that might account for the sensations, especially local swellings.

## SECOND DAY.

DR. J. A. LONG, of Long's Mills, Tenn., read a paper on

## TYPHOID FEVER.

The doctor said that the invasion was insidious

during the initial stage; tongue white, smooth and glossy, tip and edges red, trembling when protruded, subsequently many changes, speckled appearance; the pulse dicrotous, in the beginning weak, and this is characteristic of typhoid fever. Headache comes on during the second week and lasts ten days. Rose-colored eruption invariably present; muttering delirium in all forms and cases of the disease. Both infectious and contagious; may be a mixed fever, as he saw in Polk Co., Tenn., without tympanitis but the pulse had a reacting beat. The causes of the disease, filth about old barns and out-houses; diagnosis so easy that there is no disease likely to be mistaken for it when symptoms are well marked, yet there are some cases which do not have well marked typhoid symptoms. There is little doubt that the first cases in a family arise from the influence of infection, and in the later ones the infection acts as a predisposing cause to the contagion of the first cases. He has no faith in the germ theory. It is the fever that kills. The report covers 505 cases with a death-rate of less than 2 per cent. His main reliance in treatment is to combat ulceration of the glands of the small intestines, which is one of the earliest symptoms, by giving turpentine in 1 drop doses every hour. Whether it acts as a diffusible stimulant to slow ulceration, or as a disinfectant, he does not pretend to say.

The paper was discussed by Drs. G. W. Drake, J. E. Purdon, L. P. Barber, W. L. Gahagan, Chas. N. Cooper, R. D. Boyd, Jas. E. Reeves, H. E. McReynolds, C. Holtzclav, J. F. Lynch, J. B. Cowan and Frank Trester Smith, who presented a specimen of ulceration of the intestine.

DR. REEVES said: The paper just read, notwithstanding the long experience and high professional standing of the essayist, is defective in many particulars. As a clinical picture of typhoid or enteric fever it is so faulty, so unnatural, that those familiar with the original would scarcely recognize the specific picture, and I can only account for the warm commendation it has received on the ground that it is not easy to follow the reading of a paper on any subject with such correct understanding of its value as to enable the hearer to discuss it fairly and critically. My excuse for the criticism I shall offer is that for forty years I have been a student of enteric or typhoid fever, and by such training I am able, I think, to compare the picture just presented with one which I myself long ago gave to the profession,<sup>1</sup> and which to-day I could not improve, notwithstanding the greater clinical experience gained in the last twenty-five years.

I do not know a typhoid fever in which the "headache comes on in the second week, a dicrotous pulse during the initial stage without cough

and bronchial râles; muttering delirium in all cases, where cause of the disease is filth about old barns and out-houses, where "*the first cases in a large family arise from the influence of infection, and in the later ones the infection acts as a predisposing cause to the contagion of the first cases,*" and where "ulceration of the glands of the small intestine is one of the earliest symptoms." This is wonderful! He has so far modified the turpentine plan of treatment given by the never to be forgotten master in the theory and practice of medicine, the late Prof. Geo. B. Wood, that he recommends but 1 drop of turpentine every hour "to prevent the ulcers from getting headway." He relies upon this dose of turpentine as a diffusive stimulant, to slow ulcerations or to disinfect microbes! He contradicts himself in some of his statements, *e. g.*, after saying "the diagnosis is plain and easy when the history, symptoms, etc., are studied," he declares "some cases have no well marked typhoid symptoms." Finally, he boasts that his fatal cases have not exceeded 2 *per cent.*! and this is the answer that he himself makes to the question that naturally suggests itself—Were his cases all genuine cases of typhoid fever? I am sorry to have felt myself compelled to make these remarks, but the demands of medical truth are inexorable, and I must beg that my criticisms go on record with the paper.

DR. DRAKE said that the paper contains the most complete pen picture of the disease which had ever been presented to his mind, and barring some confusion in regard to infection and etiology, merited high commendation. Much interest attaches to the paper as being the result of the observation of over 500 cases in a practice of forty-five years in the same locality. Dr. L. gave his own observations of his cases without reference to text-books or the experience of others. Turpentine, quinine, alcohol, milk and home-made beef-tea are the medicines and foods Dr. Drake had used in his practice.

DR. W. C. TOWNES, of Chattanooga, read a paper on

#### HYPNOTISM AND SUGGESTIBILITY.

Dr. Townes had recently studied the subject of hypnotism in Paris, and claimed that it was a means that had too long been relegated to charlatans. In support of his claim that it should be recognized he cited several cases where patients had been cured by this mysterious agency. He showed that the phenomena of moving tables, etc., are real, that certain of our actions are made unconsciously, dependent upon complicated brain action and also on double personality. Hypnotism is a peculiar psychical state which we are able to create in the subject and which increases his suggestibility. From a medical standpoint the aim is to produce this state, so that suggestion will excite the nervous system to perform acts

<sup>1</sup>"A Practical Treatise on Enteric Fever, its Diagnosis and Treatment; being an analysis of 135 consecutive cases derived from private practice and embracing a partial History of the Disease in Virginia." Philadelphia: J. B. Lippincott & Co. Pp. 200. 1859.

that will lead toward a cure. Homœopathy, miraculous waters, granules and Brown-Séquard's elixir of life act by suggestion, often resulting in a cure. The author closed by citing the conclusions adopted by the recent Congress in Paris: that hypnotism should be taught in medical schools, but should be under authoritative administration.

DR. J. E. PURDON, of Cullman, Ala., read a paper entitled

THE SPHYGMOGRAPH AS A NEW REAGENT IN  
PSYCHICAL RESEARCH.

Dr. Purdon's paper had for its object the advancement of a claim to the discovery of the fact that psychical influence of one nervous system upon another at a distance, and unconnected by any of the ordinary physiological bonds, could be demonstrated by the aid of the sphygmograph. He claimed to have identified in many instances forced relationships of the pulse tracings from the fact that certain neurotic subjects had departed from their usual trace forms to conform to those of individuals with a more dominant nervous system. Dr. Purdon further argued that this was a first step towards the proof of physical connection between the higher centres of different brains which the progress of modern psychology obliges us to acknowledge, in the face of the now well established fact of psychical community, mind reading, sympathetic sensibility, etc. He argued against the fundamental principles of materialism by falling back upon the possibilities of the infra-conscious intelligence and by regarding mind and matter as but different aspects of the one underlying reality.

These two papers were discussed by Drs. G. W. Drake, James E. Reeves, J. B. Cowan and G. A. Baxter.

DR. DRAKE said: We have heretofore been taught that nerve impulses are confined to the individual in whose organism are contained the cerebro-spinal and ganglionic nervous systems. In Dr. Purdon's paper the startling thought is presented that nerve impulses (or nerve fluid) may escape from the body of one individual and, like electricity, passing through the intervening media, atmosphere or even a stone wall, penetrate the body of another individual. When impulses from the cardiac centres of one person may pass to those of another, or to the nerves leading from them, and so control the pulse as to cause the sphygmographic tracings of the individuals to be essentially identical; when impulses—a current of fluid—as instanced in the cases of the prisoners cited in Dr. Purdon's paper, passed through prison walls and affected individuals in separate cells; this fluid must be more subtle than electricity, since the latter might have shattered the walls, while there was no trace left in the walls by the passage of the nerve influence, but the

doctor shows traces of the sphygmograph claimed by him to have been caused by impulses which passed through the walls. There were peculiar noises in the room when Dr. Purdon made these observations on the three prisoners, like rappings on tables, noises produced by the passage of this subtle fluid (nerve impulse) through non-conducting media which would be encountered here and there in the atmosphere of the room; little thunders, as it were, analogous to the thunder of lightning. Dr. Purdon appears to teach that currents of thought may pass from one brain to another, as in mind reading, and currents of painful impulses from a parturient woman to a sympathetic spectator, and during pregnancy the husband may suffer, by transference, the nausea which belongs to the wife. If Dr. Purdon's theories be true, how may we know that our thoughts are our own and not currents of impulses from the brains of others? This is a legitimate inference from his theories.

As to hypnotism and suggestibility presented by Dr. Townes; the brain centres are kept awake and active by impulses which flow in through the five senses, and also by thoughts or ideas from the mind—a separate existence from matter—impulses may be conducted by nerves to any or all of the brain centres, or subconscious impulses may originate in these centres. Now, then, if these centres, either by impairment of the centres so as not to receive impulses or impairment of the nerves so as not to conduct them, or the shutting off of the stimuli so as not to act on the peripheral terminations of the nerves, the centres thus treated are in a hypnotic state, while other centres may be awake and active. There may be thus localized hypnotism. To become an expert in the practice of hypnotism it is necessary to study the methods of temporarily suspending or retarding the action of the brain centres. If you have to control a normal action in the subject, by the same means you may be enabled to modify an abnormal action which is producing some functional disturbance. The quieting of the fretful babe by the mother's gentle patting and sweet lullaby is due to hypnotism, and later the aches and pains are cured by the mother's kisses—suggestion. The method by suggestion is a species of faith cure and depends in a great measure on the credence of the patient in the promises of the physician. Suggestibility, as I understand it, is a susceptibility to certain psychical influences, and may be increased by the hypnotic state. Hypnotism and suggestibility are old ideas clothed in the habiliments of science. Let us beware how we handle the tool of the charlatan lest we give our endorsement to methods we strenuously condemned in the near past. Psychology is destined to work great revolutions in medicine, but let us take our soundings often as we near shoal waters.

*(To be concluded.)*

## DOMESTIC CORRESPONDENCE.

## LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

*New York County Medical Association—The late Professor Alexander B. Mott—A Double Fetus—Podalic Version in Contracted Pelvis.*

At the last meeting of the New York County Medical Association Dr. John Shrady read a memoir of the late Professor Alexander B. Mott, which was listened to with much interest, and at its conclusion the following minute was adopted:

In the death of Alexander B. Mott the well-maintained heritage of a name illustrious in the annals of surgery is transmitted to posterity with added memories of good work faithfully done.

Self-reliant, ingenious in device, and exceptionally skilful in execution, his career exemplified the best attainment of his chosen art, and his departure leaves a vacancy long to be deplored.

Sharing the grief of the whole profession which he adorned, this Association desires to record its special regret for the loss of a valued member, and its sympathy with those who mourn not alone for the distinguished surgeon, but for the beloved relative or dear friend.

Dr. Augustin M. Fernandez then presented a specimen of double foetus united at the thorax and upper part of the abdomen, relating the circumstances of its birth, which was attended by himself in September, and giving an admirable *résumé* of the existing knowledge in regard to such monsters and their delivery. The mother, a Cuban lady who was stopping temporarily in New York on her way to the Paris Exposition, was past the sixth month of pregnancy, and when Dr. Fernandez made his first examination he was surprised to find three feet protruding from the os uteri. A physician from the house-staff of the New York Hospital, which was near by, was hastily summoned in consultation, but there was no special trouble in the delivery, though the monster was born dead. One of the children measured 14 inches in length and the other 13½ inches; weight 4¾ pounds. They were both males and well developed, and their faces were turned toward each other. The placenta was delivered twenty-five minutes after their birth, and there was but a single umbilical cord. The uterus contracted well and the mother made an excellent recovery.

This double foetus belonged to the order of symmetrical navel-joined monsters (Fisher), in which the band of union varies from a comparatively narrow band, as in the case of the noted Siamese twins, to complete union of the thorax and a considerable portion of the abdomen. In this instance it involved the sternum throughout and all the upper part of the abdomen, there being but a single liver, which was of large size. Dr. Fernandez, in studying the literature of the subject since he met with this case, has found,

like Playfair, that the authors who have placed on record the birth of double monsters have generally occupied themselves more with a description of the structural peculiarities of the foetuses than with the mechanism of their delivery, so that, although the cases to be met with in medical literature are very numerous, comparatively few of them are of real value from an obstetric point of view. For obstetric purposes Playfair confines his attention to four principal varieties of double monstrosity, which are as follows: 1. Two nearly separate bodies united in front, in a varying extent, by thorax or abdomen (as in the present instance). 2. Two nearly separate bodies united back to back by the sacrum and lower part or the spinal column (as in the case of the "double-headed nightingale," Millie Christine). 3. Dicephalous monsters, the bodies being single below, but the heads separate. 4. The bodies separate below, but the heads fixed and partially united.

The principal paper of the evening was by Dr. George Tucker Harrison, Vice-President of the Association, on "Podalic Version in Contracted Pelvis," and embodying, as it did, the results of careful and accurate observation by an accoucheur of high reputation and widely extended experience, it constituted a contribution of real worth and great practical interest.

Dr. Harrison commenced with a reference to the very vague and indefinite views of the average practitioner as to when forceps, version, craniotomy, Cæsarian section, or the induction of premature labor are indicated in cases of narrow pelvis, and said that this was scarcely to be wondered at, considering the divergence of opinion existing among distinguished authors and teachers regarding the therapeutical doctrines of this condition. From several passages in the writings of the ancient Celsus he thought it was evident that that celebrated author had a knowledge of podalic version, and a passage from Philumenos showed that in head presentations, when these obstacles to the birth occurred, it was practiced by the Roman physicians. With the destruction of the Roman empire its literary and scientific knowledge disappeared, and it was therefore, he said, an inestimable boon that Ambroise Paré conferred on humanity when he rescued this method from oblivion and recommended its use as a conservative measure in dystocia from pelvic contraction.

Having paid a tribute to the zealous and successful labors of de la Motte on behalf of podalic version, he proceeded to speak of those of Sir James Y. Simpson, and designated as epoch-making his writings on this theme. At a meeting of the Obstetrical Society of Edinburgh, held in January, 1887, this distinguished authority had the opportunity of showing to the members a large infant extracted the previous evening by

the operation of turning through a pelvis the brim of which was greatly contracted. Although the child was born dead, the fact that the head had passed the contracted brim undiminished gave him an incitement to further investigations. In writing of this case afterward he said that it was, at the time of its occurrence, one of intense interest to him in two points of view: First, it was the first case in which he or any other accoucheur had ever tried the effects of ether inhalation during labor; second, the case appeared to him to be one of great moment as an opposite illustration of views which he had been previously led to entertain as to the possibility and propriety of substituting, in some instances, extraction by the feet for extraction by the crochet; the delivery of the infant by the hand of the accoucheur, instead of its delivery by instruments; the lateral compression of the child's head by the contracted sides of the pelvis, instead of its more dangerous oblique or longitudinal compression by the long forceps; and, above all, the transient and not necessarily fatal depression of the flexible skull of the fœtus for the destruction and necessarily fatal perforation of it.

Simpson thus summed up and recapitulated the advantages obtained by podalic version in contracted states of the pelvic brim:

1. The fœtal cranium is of a conical form, enlarging from below upwards, and when the child passes as a footling presentation the lower and narrow part of the cone-shaped head is generally quite small enough to enter and engage in the contracted pelvic brim.

2. The hold which we have of the protruded body of the child, after its extremities and trunk are born, gives us the power of employing so much extractive force and traction at the engaged fœtal head as to make the elastic sides of the upper and broader portion of the cone (viz: the bi-parietal diameter of the cranium) become compressed and, if necessary, indented, between the opposite parts of the contracted pelvic brim, to such a degree as to allow the transit of the entire volume of the head.

3. The head, in being dragged downwards into the distorted pelvis, generally arranges itself, or may be artificially adjusted so that its narrow bi-temporal instead of its bi-parietal diameter becomes engaged in the most contracted diameter of the pelvic brim.

4. The arch of the cranium or head is more readily compressed to the flattened form and size required for its passage through a contracted brim by having the compressing power applied, as in footling presentations and extraction, directly to its sides or lateral surfaces, than by having it applied, as in cephalic presentations, partly to the lateral and partly to the upper surfaces of the arch.

Lastly I may add, as a result of the whole

mechanism, that the *duration* of the efforts and sufferings of the mother is greatly abridged by turning, when used as an alternative for craniotomy and the long forceps, and that thereby her chances of recovery and safety are increased.

Simpson's teachings, Dr. Harrison went on to say, met with a hearty reception in Germany, and it was especially through the brilliant and enthusiastic advocacy of these doctrines by Schröder and Gusserow that they received general recognition on the part of the German obstetricians. In England such high authorities as Barnes, Braxton Hicks, Leishman and Duncan had employed version to a greater or less extent, while others equally well known gave the preference to the high forceps operation. In France version had never been a favorite procedure, and especially since the introduction of the Tarnier forceps had it lost ground. In this country version has found comparatively few advocates, except within restricted limits. For the value of their contributions the names of Taylor, Goodell and Lusk were worthy of special mention, and the latter, in his excellent text-book, had discussed the subject in a spirit of judicial fairness.

Dr. Harrison criticized with much vigor the article by Dr. Cameron on "Forceps vs. Version" in the American system of obstetrics, from which he quoted the following passage: "Except in cases of considerable pelvic contraction the forceps operation may be regarded as comparatively harmless in skilled hands, while internal version is always a serious undertaking, involving more or less danger for mother and child, even when performed with the greatest skill. The unpracticed operator is far less likely to do harm with the forceps than with version. Whenever, then, it comes to be a question of choosing between forceps and internal version, the forceps should be selected, unless specially contra-indicated, because the operation will be easier and at the same time safer for the mother and child." More false doctrine, Dr. Harrison thought, could hardly be embraced within the same number of sentences. Schröder had shown in the clearest manner that this putting in contrast forceps and version is an error, and ignores true obstetric relations. When version was still practicable, the forceps was contra-indicated; and when, on the other hand, the forceps was indicated, the time for turning had already passed. The objections to the use of the forceps in high-standing head were mainly twofold. In the first place the forceps grasps the head in the fronto-occipital diameter, so that the tendency is to enlarge the transverse diameters, which have to pass the conjugata, and at the same time to prevent the over-riding of one parietal bone upon the other. In the second place it is not in the power of the forceps to accomplish the inflexion of the bones, which is an important factor in the moulding of the head.

The advocates of podalic version in contracted pelvis, he said, were divided into two parties, according as they respectively formulated the therapeutic indications. The one side recommended waiting, so long as the passage of the child's head appears possible and devoid of danger; when further delay is no longer permissible in the interests of the mother, perforation and extraction with the cranioclast in high-standing head; forceps in the case of a living child, after the narrow part has been surmounted; in unfavorable engagement at the brim, fixation not ensuing within a certain period, version and extraction. The other side sought to avoid the possibility of a perforation by a prophylactic version before any symptom of danger threatened the mother. Dr. Harrison said that for years his own practice had been based upon this view, and that he could not earnestly advocate the advantages of this method of procedure. Long ago Simpson had argued that the protraction of labor was, *per se*, dangerous both to mother and child, and that any operation was dangerous and fatal in proportion to the length of time allowed to elapse before the artificial delivery was accomplished. For these reasons he declared that in proportion as turning was practiced earlier, so far would it be attended by greater safety and greater success.

The conditions most favorable for version were, of course, intact bag of membranes and completely dilated os uteri. Often, however, the physician was not called to the case until the membranes had already ruptured, and this might have occurred prematurely. This premature rupture was especially to be regretted in a contracted pelvis, as it rendered the prognosis for mother and child more unfavorable, the explanation being that such an accident is more apt to occur at an early stage of the labor in a narrow pelvis. He fully agreed, therefore, with Nagel in the opinion that in a premature rupture of the membranes version should be undertaken as early as possible, and that we should not wait for full dilatation. It was of the utmost importance, as influencing the result, that the after-coming head should be brought through the pelvis with as little delay as possible, and upon the best method of accomplishing this the views of different authors were at variance. All were agreed, however, that the head must be guided into the pelvis and drawn through it with the chin flexed. The finger in the mouth served mainly to approximate the chin to the breast. A supremely important matter was the pressure from without through the abdominal coverings, traction on the trunk being made by the hand over the nape, according to the Veit method. Dr. Harrison's experience has been entirely in accord with that of Nagel, who suggests the propriety of rotating the chin behind, when still in the inlet of the pelvis, so that

the sagittal suture runs in one or the other oblique diameter. In this way, he said, he had repeatedly accomplished delivery in exceedingly contracted pelves.

In the discussion of the paper Dr. Charles A. Leale described the method he pursued in inducing premature labor and delivering by version in cases where the pelvis was contracted to such an extent that it was not deemed expedient to allow the woman to go to full term; and Dr. Joseph Kercher spoke particularly of the difficulty in correctly estimating the pelvic diameters, stating that he had known good obstetricians to resort to the early use of version or the forceps in cases where the pelvis was in reality of normal size, under the impression that there was present a considerable degree of contraction. In his opinion podalic version was not to be recommended, as a rule, in primiparæ, except the os were well dilated and the membranes unruptured; breech labors being much more dangerous to the latter than to multiparæ.

In closing the discussion Dr. Harrison spoke in deprecation of the emphasis which most of the text-books on obstetrics laid upon the rarity of contracted pelvis in this country as compared with European nations. It was, no doubt, true, he said, that this condition was somewhat less common here than in Europe, but at the same time it was met with with sufficient frequency to make it necessary that every practitioner of midwifery should be fully prepared to treat such cases in the most skilful manner. Personally he had had some terrible experiences with them in this city, and as every one was liable to come across them in his practice, he thought it was a great mistake that the student and young physician should be allowed to get the idea that they were so rare that he need regard the chance of his encountering one as only a remote contingency.

At this meeting, which was the first the Association has held since the long vacation, twenty-nine new members were elected, and a committee was appointed to consider and report upon the best methods of suppressing illegal practitioners and mitigating dispensary abuses in the city of New York.

P. B. P.

#### Chloroform Accidents.

*To the Editor:*—I take the liberty of writing you in regard to the article on "Chloroform Accidents" in *THE JOURNAL* of October 19th.

I have been for many years following the practice there described for prevention of death under anæsthetics, and have over and over again presented it to the profession of this country. First in the *American Journal of Medical Sciences*, April, 1876, on "The Influence of the Injection of Narcotics upon the Anæsthetic Process;" again in "Transactions of the State Medical Society of

Ohio," 1879, in which paper I particularly urged the influence of atropia in sustaining the heart's action; further, in American edition "Holmes' Surgery," and several times in journals.

Now, I do not wish to trouble you, and care little about the *personal* honor of priority in this matter, but think that when a procedure is published as a *good thing*, being so discovered *abroad*, those who have worked at it for many years before in *this country* deserve mention.

In speaking of *priority* of this process, I do not claim *originality*, but only that I have been a persistent and repeated advocate of it. I believe it to be one of the most important and most valuable modifications of the anæsthetic process. Nussbaum first used it. When in Munich, in 1887, I took the trouble to call upon him in reference to it, but found that he never carried it beyond his first essay.

The method was placed upon a scientific basis by Bernard ("Leçons sur l'Asphyxie et l'Anæsthetic"), and the results as to death of dogs there given is quite as striking as that in the article you have published.

I am very respectfully and truly yours,  
J. C. REEVE, M.D.,  
Dayton, O., October 19, 1889.

#### Tenth International Medical Congress.

To the Editor:—I have received the following letter from Professor Virchow, the President-elect of the next Medical Congress.

Very truly yours,  
JOHN B. HAMILTON.

Treasury Department, U. S. Marine-Hospital Bureau,  
Washington, D. C., October 30, 1889.

BERLIN, October 1, 1889.

Dear Sir:—The Organizing Committee of the Tenth International Medical Congress is now constituted. I myself am elected President, and Dr. Lassar (Karlstrasse 16, N.W.) Secretary-General. We will be very happy to receive the Transactions of the Ninth International Congress, and we hope to see you and many of your countrymen at the new session.

I am, sir, very sincerely your obedient servant,  
PROFESSOR RUD. VIRCHOW.

#### Holland Claims the Microscope.

To the Editor:—Allow me to call your attention to an error in THE JOURNAL of September 14th, which mistake I have recently seen in one or more other journals. On page 385 of THE JOURNAL, under the caption of "The Tercentennial of the Microscope," you ascribe the invention of that highly useful instrument to a Zacharias Janssen, of Magdeburg, the capital of a Prussian province, Saxony. Zacharias Janssen, to whom belongs the credit of constructing the first *compound* microscope (the simple microscope was known previous to that time), was not a German but a *Hollander*, born and reared in *Middelburg*,

the capital of the province of Zeeland, one of the eleven provinces of the United Netherlands.

Germany and the Germans seem particularly anxious to monopolize the credit of most of the *useful* inventions—now they lay claim to the invention of the microscope. "Honor to whom honor is due."  
J. VANDERLAAN, M.D.

Muskegon, Mich., September 14, 1889.

#### NECROLOGY.

##### Dr. Isaac E. Taylor.

This distinguished physician, so well known to the medical profession and so highly honored, died at his residence in West Thirty-fifth street, New York City, on the 30th ult., at the age of 77 years. He was from the time of its organization until his death the first and only President of Bellevue Hospital Medical College, and has always been esteemed as one of the foremost promoters of medical education.

About ten days previous to his death he was attacked with acute pericarditis and was confined to his bed. Up to the moment of death he had not been considered seriously ill. While lying in bed and reading from a book his daughter noticed that he suddenly threw his hand over his head, sank into his pillow and in three-quarters of an hour he was dead. Mrs. Taylor died in 1867. Four children—Mrs. Pierre Lorillard, Col. Stewart Taylor, Mrs. Hilliard M. Judge, and an unmarried daughter, are his immediate surviving relatives. His was a well rounded life, full of years, of unusual achievement and of signal honors. To the family bereaved and to the Faculty of the College, the profound sympathy of the profession will be most freely accorded.

##### Dr. L. F. Warner.

DR. LEVI FARR WARNER, of Boston, for many years an influential member of the American Medical Association, and in 1874 one of its Vice-Presidents, was born Oct. 25, 1822, at Norwich, Chenango Co., N. Y. He died Oct. 12, 1889, at Boston, two weeks before the completion of his 67th year. Educated preliminarily at the Academy at Mexico, N. Y., he studied for his profession during 1842-3 at Geneva Medical College, and subsequently graduated in 1862 at Lind University, Chicago. He commenced practice at Vienna, at Oneida Co., N. Y., and removed thence to St. Louis, where during the war he was Ass't Medical Examiner for the First District of Missouri. He then came to Boston, and was admitted a member of the Massachusetts Medical Society. He was one of the founders of the Gynecological Society of Boston, and soon became recognized as of especial skill in the diag-

nosis and treatment of the diseases of women. He conducted successfully a large practice until his death, which was from cerebral hæmorrhagic effusion, the result of an accident.

Though always participating with interest in the discussions at the various scientific societies with which he was connected, he wrote but little, save quite a number of obituaries of deceased members of the American Medical Association. His paper, however, "On the Connection of the Hepatic Functions with Uterine Hyperæmias, Flexions, Congestions and Inflammations" in the Transactions of the American Medical Association for 1878, vol. xxix, exerted a distinct influence towards obtaining in New England a wider respect by general practitioners for the specialty of gynecology, then still upon trial, and at the same time served to curb the somewhat inordinate zeal of a portion of its younger enthusiasts.

The writer of this notice was long associated in practice with Dr. Warner, and the relation was of the most intimate character. From first to last he was always faithful to his duties. Not a shadow of difference ever arose between the two, and there was never an unkind word uttered. Scotch in his parentage, several of the most important traits in his character were doubtless inherited. His father a clergyman, he knew the Scriptures absolutely, and they were ever in his mind. He was Presbyterian from childhood, but towards the end of his life held close relations with the Congregationalists, with whom his lately deceased wife was in communion. He enjoyed in a pleasant way religious controversy, but it was rather as a kind teacher than as an antagonist.

He was one of the most genial of men. Full of anecdote to overflowing, cheerful and merry by nature, he carried comfort to the despondent even when his own disappointments and sorrows, and he had many of them, were weighing most heavily upon him.

He was almost perfection itself in his chosen professional work. Always successful in obtaining the full confidence of a patient, he never proved unworthy. He was untiring, in the most chronic and discouraging cases, to a marked degree. Persistent in following up the instances of this kind that were confided to him, he often produced the most surprising and unexpected cures, restoring women to their full usefulness who had for many years apparently been hopeless invalids. At his funeral there were scores of such, who dated their restoration to domestic happiness and to life itself, a long time back, wholly to him, and so lamented their loss accordingly.

To those who treated him fairly he was devoted in his friendship. He was true as steel, and as gentle as a child. Though naturally sensitive and quick tempered, he was always

ready to make acknowledgements if it should prove that he had been in error. He disliked to have wealthy patients, declaring that in the middle-class one found the most gratitude. To the poor, both in private and hospital practice, he always gave freely of his thought and time, and had he not, besides, contributed much and constantly in other charity, he would have amassed a fortune from his profession.

He has left instead a better legacy, the loving recollection of a thoroughly upright and honest man, a most delightful companion, an always reliable friend, a really good physician. *May he rest in peace.*

H. R. S.

## BOOK REVIEWS.

A SYSTEM OF OBSTETRICS. By American authors. Edited by BARTON COOKE HIRST, M.D., Associate Professor of Obstetrics in the University of Pennsylvania, Obstetrician to the Philadelphia and Maternity Hospitals, etc. Vol. II, illustrated with 221 engravings on wood. Pp. xi, 854. Philadelphia: Lea Bros. & Co. 1889.

The second volume of Hirst's splendid System of Obstetrics forms a valuable contribution to the American literature of this subject. In subjects where recent advance has been made, as in the study of the bacteriology of puerperal fever, the more recent views of the authorities are set forth with a minuteness of detail which is nowhere else to be found in obstetrical works. Indeed, were it not for the work of the bacteriologists of the present day, it would be difficult for obstetrical writers to find anything new to offer their readers, and in point of fact some of the recent publications, with all their pretensions, will be found to have made but very little improvement on their editions of a dozen years ago.

Like all works of the character of the one under consideration, there is a lack of consecutiveness and balance in the arrangement and treatment of the several topics, while on the other hand there is a certain advantage in becoming familiar with the views of a number of authoritative writers.

The present volume contains valuable articles by Dr. Theophilus Parvin, on the "Diseases and Accidents of Labor;" articles on "The Forceps" and "Embryotomy," by Dr. E. G. Davis; articles by Dr. Jas. C. Cameron on "The Premature Induction of Labor," and "Version" (would it not have been better to have said the "Induction of Premature Labor?"); an article on the "Cæsarean Operation, Symphysiotomy, Laparo-Elytrotomy and Laparo Cystectomy," by Dr. Robert P. Harris; "Inflammation of the Breast and Allied Diseases Connected with Childbirth," by Dr. Henry J. Garrigues; "The Etiology of Puerperal Fever," by Dr. Harold C. Ernst;

"Some Complications of the Puerperal State Independent of Septic Infection," by Dr. Barton Cooke Hirst; "Insanity and Diseases of the Nervous System in the Child-bearing Woman," by Dr. Jas. Hendric Lloyd; "The Management and the Diseases of the Newborn Infant," by Dr. J. Lewis Smith; "The Surgical Diseases of Infancy and Childhood," by Dr. Stephen Smith; "Congenital Anomalies of the Eye," by Dr. G. E. De Schweinitz.

It will be noticed that some of these contributions are a little outside the strict limits of obstetrics, but the reader will find that the value of the work to the practitioner has been greatly enhanced by the addition of these excellent chapters.

## MISCELLANY.

CHAS. CHADWICK, Ottis R. Wyeth, Louis A. Schoen, Geo. J. Schoen, Chas. F. Hermann, Geo. Eyesell, and Horace L. Roy, druggists of Kansas City, Mo., were recently fined \$500 each and costs for counterfeiting a preparation known as bromidia.

Maynard, Los Angeles, Cal.; Dr. B. M. J. Conlin, Alexandria, Dak.

## Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 2, 1889, to November 8, 1889.

By direction of the Secretary of War, Major Robert M. O'Reilly, Surgeon, will, at the expiration of his present leave of absence, proceed to Ft. Logan, Col., and report in person to the commanding officer of that post for duty. Par. 6, S. O. 256, A. G. O., November 2, 1889.

Capt. James C. Merrill, Asst. Surgeon, is relieved from duty at Frankford Arsenal, Pa., and ordered to duty at Ft. Reno, Ind. Ter. Par. 6, S. O. 256, A. G. O., November 2, 1889.

Capt. Charles S. Black, Asst. Surgeon, is relieved from duty at Ft. Sidney, Neb., to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer, Ft. DuChesne, Utah. Par. 6, S. O. 256, A. G. O., Washington, November 2, 1889.

Capt. R. W. Johnson, Asst. Surgeon, granted leave of absence for one month, to take effect on or about November 10 prox. Par. 4, S. O. 110, Dept. of Ariz., Los Angeles, Cal., October 29, 1889.

By direction of the Secretary of War, leave of absence for two months on account of sickness, with permission to leave the Div. of the Missouri, is granted Capt. Junius L. Powell, Asst. Surgeon. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1889.

Lieut. F. J. Ives, Asst. Surgeon U. S. A., granted two months' leave of absence. Par. 3, S. O. 256, A. G. O., November 2, 1889.

## Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 9, 1889.

Surgeon B. F. Mackie and Asst. Surgeon Geo. McC. Pickrell, detached from the U. S. S. "Ossipee" and placed on waiting orders.

### THE SO-CALLED THIRD TONSIL. ITS IMPORTANT RELATIONS TO NASO- PHARYNGEAL AND NASO- AURAL CATARRH.

*Read before the Section of Laryngology and Otology, at the Fortieth Annual Meeting of the American Medical Association, at Newport, June, 1889.*

BY JOSEPH A. WHITE, A.M., M.D.,

SENIOR SURGEON OF THE RICHMOND (VA.) EYE, EAR, THROAT  
AND NOSE INFIRMARY.

It would seem to be an unnecessary and superfluous task to present a paper on this subject before an assembly of specialists in nasal, aural and throat diseases, but as all our knowledge in medicine is the result of the aggregate experience of different observers, I would crave your indulgence whilst I add my mite to the general fund.

Much has been written of late years on Luschka's tonsil, adenoid tissue, lymphoid vegetations, etc., and whilst the fact that *deafness* sometimes results, especially in children, from any excessive accumulation of this formation, no particular stress has been laid on the active influence it exerts in the production and aggravation of naso-aural and naso-pharyngeal troubles, even when present in a slight degree only.

Whilst it may be true, as stated by so many observers, that the presence of glandular hypertrophy in the post-nasal space is the frequent result of a previously existing catarrhal condition of its mucous lining, my experience would lead me equally to the opposite conclusion, that the presence of this glandular hypertrophy, however produced, and however little, is an active agent in keeping up a more or less so-called catarrhal condition of the mucous lining of the post-nasal space, and its extensions into neighboring cavities, especially the ear. That this is true of nasal polypi, we all admit. They may be produced by a nasal catarrh, but once there the catarrh cannot be cured without their removal. This holds equally good of hypertrophied *faucial* tonsils even when only moderately enlarged. I have found, if I wish to get rid of a naso-pharyngeal or aural catarrh in the presence of enlarged

tonsils, I must either remove or destroy this hypertrophied tissue as a means to that end. I have often been astonished at the rapid improvement, after this was done, of cases that had previously resisted all methods of treatment.

Even when there is no perceptible enlargement of the tonsils, I frequently find it necessary, as a means to the same end, to destroy what might be called the normal glandular tissue between the pillars of the fauces, especially when there is a constant, or, even occasional exudation of whitish secretion from the follicles, a condition generally known as "chronic follicular tonsillitis." In such cases it is my habit to introduce a fine galvano-cantery point, or chromic acid into the succulated follicle and set up adhesive inflammation.

The rôle played by the tonsils in the human economy is a question in considerable doubt, and the attempt of some writers to show that they are "leucocyte manufactories" has not had the support of demonstrative facts. There is no question of their having *some* function to perform, but we don't know its value or importance. We do know that the decided presence of this glandular tissue, whether faucial, pharyngeal or lingual is nearly always accompanied by some pathological manifestations, and that their absolute destruction is followed by no disaster to the individual, but in a very large proportion of the cases, by decided benefit.

Possibly, the so-called third tonsil plays a more important rôle in the production of aural and naso-pharyngeal troubles, with secondary laryngeal changes and reflex manifestations, than the faucial or lingual tonsils combined.

It is easy to understand how *deafness* may result from any excessive glandular hypertrophy, or, any great development of adenoid tissue at the pharyngeal vault, because it then acts practically as a *direct* impediment to the proper ventilation of the Eustachian tubes. This is sometimes the case, even where nasal breathing along the lower meatus is comparatively easy; but more frequently so, when the hypertrophy or tissue blocks the post-nasal openings as well. I have seen cases, as all of my hearers have also, where the post-nasal space was completely obliterated by masses of soft fungous tissue growing from vault,

back and sides, and projecting below the arches of the soft palate. One would suppose that such a condition of affairs would eventually lead to great and irremediable deafness, if these masses were not soon removed, and it is probable that it *might* do so, but it is not in accord with my experience.

I have seen quite a large number of cases of excessive development of this soft lymphoid tissue in the last ten years, but have never seen but *one case* where it caused marked permanent deafness, and that was in a man 48 years old, from whose history I should conclude that he had been in that condition all his life. The removal of the tissue, and the treatment of the resulting middle ear catarrh very much improved his hearing power, but his deafness was still quite noticeable. The cartilaginous mouths of the Eustachian tubes had been permanently deformed, and the palato-tubal muscles paralyzed by the long continued pressure, and their long inaction.

Paresis of the palate and palato-tubal muscles is one of the results of this condition, and may bring on, independent of any changes in the drum cavity or tube, what Weber-Liel long ago described under the heading of "paretic deafness;" and, the removal of the tissue should be followed by a course of electricity, to restore as far as practicable proper tone to these muscles.

Marked depreciation of hearing is nearly always present in these cases of great development of soft lymphoid tissue, but it is easily remedied by the ordinary treatment of Eustachian and tympanal catarrh, although I doubt if absolutely perfect hearing is ever restored. I have just finished the treatment of a young man 20 years of age, who has been very deaf all his life, from such a blocking up of the post-nasal space, and a three months treatment with removal of the tissue from vault, sides and back of the space has entirely restored hearing, although the resulting naso-pharyngeal catarrh is not yet cured.

We have, however, other forms of hypertrophy of the glandular tissue at the vault and sides of the post-nasal space. Instead of a mulberry looking mass, there may be only a small rounded projection from the vault, or a cone-shaped body with its apex downward, or two rounded lobules at either side with a marked sulcus between them, or several small knob-like outgrowths, or a flat cushion-like mass padding up the vaulted roof into a plane low pitched ceiling, and extending from side to side, and from front to back without obstructing the post-nasal openings. Sometimes these are composed of soft tissue easily removed, and sometimes they are dense and hard.

I have found that the Eustachian tubes are more especially injured by such a tissue when they are of a firm dense consistence than when soft. The resiliency or elasticity of the cartilaginous openings is seriously damaged by the pressure

of these masses, particularly when they extend or grow *above and behind the tubes*, and the invariable accompanying catarrh of the naso-pharynx by extension to the middle ear adds to the impairment of hearing. Such cases I find more difficult of a *restitutio ad integrum*.

It is probable that the percentage of impaired hearing accompanying hypertrophy of the third tonsil is greater than we would suppose, because slight defects of hearing would most likely be overlooked by both patient and physician, and our statistics therefore only include cases where this defect has become clearly noticeable. If aurists would invariably look for such hypertrophy in all cases of middle ear disease, suppurative or non-suppurative; if rhinologists would always test the hearing power carefully, whenever they find such hypertrophy present, we would soon get accurate statistics on this subject.

Since I have made my "self-retaining palate retractor," I invariably use it in examining the post-nasal space of all cases that present themselves for throat, or middle ear troubles, and whenever I find any hypertrophy of the third tonsil I test the hearing with the result of having, at times, found commencing deafness not previously suspected. During the last eighteen months 565 patients have applied at my private office for treatment of naso-pharyngeal and middle ear affections, of whom 197 had disease of the middle ear.

Out of the whole number 134 had hypertrophy of the third tonsil, of whom 62 cases suffered with varying degrees of deafness, *i.e.*, 20½ per cent. of the total number showed such hypertrophy, and a fraction over 30 per cent. of these had middle ear complications.

Of these 134 cases, 29 had very large faucial tonsils, 54 turbinated hypertrophy, 18 deflected septum, 22 secondary laryngitis, 46 voice troubles, 1 had atrophic rhinitis. Nearly one-half were under 21 years of age, and 25 per cent. were over 30.

Cases seen at my clinic at the Richmond Eye, Ear, and Throat Infirmary, are not included in these statistics.

It seems to me that *this proportion of 20 per cent. in the whole number of cases* is a very large one, as compared with the reports of other observers. Possibly climatic influences may have something to do with the development of this form of hypertrophy.

The 30 per cent. of impaired hearing were all decidedly deaf to the watch and low voice, although in some cases the deafness was not noticeable in ordinary conversation.

A point of special interest, in these cases, is the large number of voice troubles and laryngitis resulting from the presence of this form of hypertrophy by lowering the roof of the pharyngeal vault, thus seriously interfering with its function as the resonance space for the voice.

This, of course, is no news to any of my hearers, but I doubt, if we all give this matter the attention it deserves. As far as my experience goes, I find that all persons who use the voice habitually, such as singers, actors, clergymen, lawyers, teachers, etc., have invariably some difficulty in a prolonged use of the voice if there is any thickening of the tissues at the pharyngeal vault, even when of very slight degree. The vaulted shape of this space should be perfectly preserved, and everything removed that alters it in any way if the resonance and timbre of the voice are to be retained.

Fifty-four cases had marked turbinated hypertrophy, and only one *atrophy* of the turbinated tissues, the only case I ever saw in connection with adenoid tissue.

Among my cases of naso-pharyngeal troubles with or without aural complications, I have found that the presence of glandular hypertrophy aggravated the symptoms and caused more excessive and annoying secretion, and that many of them suffered from almost constant *headaches*, especially if engaged in any occupation requiring close mental application. The excessive secretion and the irritation resulting therefrom to the surrounding mucous surfaces, prevents any benefit from local applications, or other treatment, unless the hypertrophy itself is removed or destroyed. In this way the third tonsil has a direct and deleterious influence on any previously existing catarrh of the naso-pharynx, and produces it where it did not previously exist.

It also in the same way *indirectly* produces or aggravates a catarrh of the Eustachian tubes, when its location is such as not to have a *direct* influence on the ear. When the adenoid tissue is present in such quantity as to cause nasal stenosis, so many ill effects result from the obstruction, that all writers are of accord as to the advisability of its removal, merely differing upon the method of operation. It is useless to here rehearse the consequences of neglecting to destroy it, but allow me to mention two results from this stenosis, as affected by the operation for removal of the tissue. One is anterior turbinated hypertrophy, which I find very frequently accompanies it, and which in a larger proportion of cases disappears spontaneously after the post-nasal space has been cleared.

The other is the occasional paralysis of the *alæ* of the nose, the *dilatatores nasi* and the *compressor naris* becoming paretic, probably from non-use; and this result is a serious one, for, if of long continuance, I doubt if it is ever radically cured; at least whenever present, I have found it a serious impediment to the restoration of nasal breathing, even after the nose and post-nasal space were perfectly clear.

But whilst writers are in accord about the removal of the third tonsil, when its hypertrophy

causes nasal stenosis, there seems to be a difference of opinion when this is only of slight degree; some advocating its entire removal; and others, regarding it as a normal appendage with some unknown function to perform, being of the opinion that it is best let alone.

*Now, is the third tonsil so called an essential normal appendage of the post-nasal space, or is its presence a congenital anomaly or the result of changes in the muciparous and follicular glands?* I am sure the former question may be answered in the negative and the latter in the affirmative. I regard any tissue of any shape, whether pendent, rounded or flattened, that interferes with the vaulted aspect of the pharyngeal roof, as a congenital anomaly or a pathological formation, that ought to be removed or destroyed, because, even if it has not already brought about some naso-pharyngeal trouble, it will do so, sooner or later.

I so regard it, as, in at least 80 per cent. of the cases that have come under my observation for treatment of such troubles, there was not the slightest sign of any such formation as glandular tissue, the mucous lining of the vault being seemingly intimately adherent to the periosteum of the base of the skull. This mucous membrane has the same minute follicular and muciparous glands as the rest of the mucous lining of the throat, with a special aggregation of them in the location of Luschka's tonsil, so-called.

Any pathological process in these glands may result, as suggested by Dr. Bosworth, in sufficient thickening or hypertrophy, to change a microscopic into a macroscopic condition. The former is the physiological, the latter a pathological state. This process may be arrested with the slightest perceptible enlargement, or, go on to the development of soft fungous masses, adenomatous tumors, or even dense connective tissue growths.

With my self-retaining palate retractor in position, I have made numerous examinations of diseased and healthy post-nasal spaces, to look for some evidence of the *normal third tonsil* as also for the opening or mouth of the so-called *pharyngeal bursa*; as yet I have never found the former except in the pathological conditions referred to, and I have never been satisfied that I have found the latter at all, although I have occasionally seen and treated what might be the inflamed bursa, but which always seemed to me a dependency of the third tonsil and its pathological changes. Hence, I am still a skeptic about these parts being essential, *normal* constituents of the post-nasal space. I know I am a heretic in this respect, but crave that indulgent consideration which all true believers give to heretics on the ground of *invincible ignorance*.

Some twelve years ago in a transient visit to Dr. J. Solis-Cohen, he picked up a pair of post-nasal

forceps that he used for the removal of adenoid growths, and said in answer to some remark of mine about the danger of seizing the wrong tissues, that he considered anything they would grasp as legitimate prey. This statement fully represents my views at the present date, that any tissue at the vault which can be grasped by the cutting forceps should be removed.

I have found beneficial results follow the treatment of cases of post-nasal catarrh, after the ablation of all tissue at the vault, that had previously resisted every application.

In some cases the secretion is small in quantity, but is difficult to dislodge, and forms a small mass immediately at the vault, that soon emits an excessively disagreeable odor, as pronounced as that of ozæna.

Such cases I thoroughly cauterize with the galvano-cautery electrodes so as to destroy the glands that secrete the unpleasant exudation—as I find this the only method of doing away with this feature of the case. As to the methods of removal I think it matters very little how it is done, provided it is done thoroughly. Large masses of adenoid tissue are best removed with the galvano-cautery snare or the cutting forceps. So also of the dense hypertrophies spoken of above, but the use of the forceps is quite painful, even with a free application of cocaine.

Smaller hypertrophies, and that smooth mass of tissue so often seen lying in between the Eustachian tubes, and coming down just to the level of the superior arches of the post-nasal spaces, making a low pitched *flat roof* out of the *arching vault*, are best gotten rid of, by burning with the galvano-cautery points, or moxa-electrode, although it can also be partially removed by the forceps.

I have found my palate retractor an enormous help in such work, because the muscular movement of the palate never interferes with a perfect view of the parts whilst operating, and I have never seen a case I could not operate on with its aid, whilst without it I have often been baffled in obtaining a satisfactory view of the parts. In fact all post-nasal operations can be done better and more readily with it than without it, for it is easier to perform any surgical work by sight than to depend merely on the "tactus eruditus." I have latterly been enabled with its help to remove adenoid tissue in children 5 or 6 years of age, under the influence of cocaine instead of giving chloroform as I was formerly in the habit of doing.

#### CANCER OF TONSIL. REPORT OF CASE AND EXHIBITION OF SPECIMEN.

As malignant affections of the tonsils are comparatively rare, I thought the history of the following case would be of sufficient interest to report.

August 2, 1887, a gentleman, 58 years of age, applied to me for treatment of a throat trouble, which had been annoying him some months. The history he gave showed a gradual enlargement of the left tonsil with occasional pain until he had gotten into the following condition:

He could no longer eat solid food, and could swallow liquids only with difficulty. The pain occasionally was quite severe. His breathing was labored, and when lying down, especially if on his right side, he suffered from attacks of suffocation, that at times were very alarming. His articulation was so imperfect that it was difficult to understand him.

The examination revealed a large tumor springing from the site of the left tonsil, growing downwards so as to press on the epiglottis and almost fill the throat.

A laryngeal inspection showed paralysis of the *right* vocal cord, it being in the cadaveric position.

I removed the tumor by encircling it with a steel wire, and constricted it until its base was squeezed into a small dense pedicle. I then removed the steel wire and completed the operation with the galvano-cautery snare. The relief was immediate, both respiration and deglutition becoming almost normal. When the eschar came away, I destroyed the remains of the base with the galvano-cautery, and repeated this operation several times at intervals of some weeks until the parts had assumed a perfectly normal appearance.

Neither faucial pillar, nor any part except the glandular tissue between the pillars was involved, nor were the lymphatics implicated. The paralyzed vocal cord never entirely recovered.

Six months later I saw him again and there had been no return of the trouble. More than a year afterwards I heard from him, and he wrote that his throat was entirely well.

Part of the growth was sent to Dr. Jno. S. Billings, Curator of the Army Medical Museum in Washington, for examination, and the following report was received from Dr. Wm. M. Gray, the Microscopist: "The specimen of tumor received proves to be an epithelioma of squamous type; it probably started as a *papilloma* and degenerated into an *epithelioma*, as the cells are arranged like those in a papilloma, and are just beginning to infiltrate."

In March, 1889, my patient called on me again, suffering from dyspnoea and dysphagia. I found on examination that there had been a recurrence of the growth below and in front of the original site, involving the anterior faucial pillar, the base of the tongue on the left side, the glosso-epiglottic fold and extending down to the lower third of the pharynx. The tumor pressed down upon the larynx, pushing the epiglottis far over to the right side, and almost occluding the opening. He said the trouble had re-appeared about

two or three months previously and had developed with great rapidity.

With my galvano-cautery snare I removed as much of the tumor as possible, especially the portion pressing on the upper part of the larynx. There was great difficulty in encircling it, and I was obliged to resort to transfixion with large needles to enable me to do so. I passed a needle threaded with coarse silk as far back in the base of the growth as possible, bringing it out just in front of the epiglottis.

My cautery wire was attached to the thread and drawn through this opening. I then transfixed the anterior portion with a large needle, leaving it in position. The wire was hooked under each end of this needle passed through the caula, the current turned on and quite a large mass removed. This enabled him to breathe easier and to take nourishment, and in a few days he returned home.

I told him that nothing but palliative measures could be made use of, and that possibly a *tracheotomy would become necessary*. In the latter part of April he returned in great distress, because of the violent pain, and much emaciated and weakened by the recurring and alarming hæmorrhages, and inability to take much nourishment. The growth had not perceptibly increased and the epiglottis was as you see it now. Strange to say up to this time the lymphatics were not involved, the left sub-maxillary gland alone being noticeable to touch. Two days after his entry into the hospital, he died very suddenly of heart failure.

A portion of the growth was sent again to Dr. Billings, and on June the 8th the following report was received from him:

"Dr. Wm M. Gray reports the specimen of tumor sent as a typical hard cancer (scirrhus). He also states that he has re-examined the first specimen sent from the same case, and adheres to his original report of squamous epithelioma."

The points of special interest about the case apart from the rarity of this form of malignant disease of the tonsil, are the development of a typical hard cancer of epitheliomatous structure out of a simple papillomatous tissue, and the fact that there was no implication of the glands of the of the lower jaw and neck even to the last, although all the other signs of malignant disease were present.

DR. D. BRYSON DELAVAN, of New York, said that he believed that the large percentage of cases of adenoid disease found by Dr. White was due to the unusual care exercised by that gentleman in the examination of his cases, and that many cases of slight hypertrophy not usually considered of pathological importance were actually productive of serious results, and therefore to be included. He preferred a solid uvula retractor to

the skeleton instrument presented by the writer of the paper.

DR. JONATHAN WRIGHT said: I have used Dr. White's retractor in perhaps a dozen cases, and, at least in my experience, it has provoked violent constriction of the pharyngeal muscles and made post-nasal examination by mirror very difficult and disagreeable to the patient. Under either I should think it might well be used, as the pharyngeal muscles are more or less paralyzed. My inexperience with the instrument may have been the cause of my failures.

DR. MACKENZIE never uses the palate retractor, although it is easily conceivable that in certain cases its use may be of very great advantage. He has used Wales' method, but finds even by this process there is often gagging and salivation, which interferes with the operation. He asked how the retractor exhibited differed, except in weight, from that invented by Dr. Porcher?

DR. THRASHER: In my operations on children for the removal of the third tonsil I invariably operate under chloroform and without a palate retractor, depending simply on touch. By this means the operation can be safely, easily and rapidly performed.

DR. WHITE, in reply, said that in the remarks made, except in those by Dr. Delavan, no reference had been made to the subject matter of his paper, the other gentlemen having confined themselves to an attack on his palate retractor. As far as he was concerned he preferred to use one, because he thought it easier for him and better for the patient that he should perform his operation with a perfect view of the parts, and not trust to his *dexterity* or his *sense of touch* to avoid an error. It was simply a question of taste, as there was no question of the fact that one could see better with the retractor than without it. In answer to Dr. Mackenzie's question about the difference between his retractor and Dr. Porcher's, he would say that in general principle all were alike, but that his own was lighter and worked in an entirely different way from all others, being adjustable or alterable for each patient, and the projecting bar in front turning out of the way of the operator by a hinge-joint. Moreover, its proper use required some experience in applying it, and with such experience the objection urged against it would probably fall to the ground.

#### DILATATION OF THE STOMACH IN SYPHILIS.—

DR. JULLIEN, of Paris, has observed a number of instances in which dilatation of the stomach developed in tertiary syphilis, and believes that it was in many instances the cause of nervous symptoms which were usually attributed directly to syphilis. Large doses of the iodide of potassium are, he thinks, not infrequently the cause of the dilatation.

## DISCUSSION ON "THE INDICATIONS FOR, AND DURATION OF, THE TREATMENT OF SYPHILIS."

*Read in the Section of Dermatology and Syphilography, at the Fortieth Annual Meeting of the American Medical Association, June, 1889.*

The chairman, DR. BULKLEY, opened the discussion with a brief paper on

### THE INDICATIONS FOR AND THE DURATION OF THE TREATMENT OF SYPHILIS.

The subject selected for our discussion this afternoon is one of very great practical interest, and one upon the decision of which, in individual cases, the very gravest consequences may rest. It is one which the physician cannot shirk if he would, and one upon which it often becomes his serious duty to decide and insist, even against the will of the patient. No one can tell what results may follow to the patient or others from an imperfect treatment of syphilis, and no one can measure the amount of harm which may be escaped by the intelligent and faithful performance of duty toward one who has become infected with syphilis.

The subject, together with the side issues to which it might lead, such as the innocent acquiring of syphilis, marital syphilis, hereditary syphilis, etc., is such a great one that it cannot by any means be compassed in a single discussion, much less can I attempt any considerable consideration even of its salient points. The most that I can hope for, in the brief time which should be taken by one opening the discussion, is to suggest certain points and lines of thought along which we may proceed, leaving the background to be filled by others.

Syphilitic infection takes place from the moment when the syphilitic virus is implanted upon a surface bereft of its epidermis or epithelium; or, in other words, as soon as the poison can be reached by absorbing tissue. It is not necessary for our discussion to consider, or even to know exactly, in what manner the infective material is taken up, although it probably enters the lymphatics at once; it is sufficient for our purpose to know that when once the virus has entered the system, the person is syphilitic, and if the course of the disease is not influenced by extraneous forces it will, in the large proportion of cases, develop in a certain manner, and run a more or less definite course, the natural history of which is now pretty well known and described. This course, beginning with the chancre or primary lesion, and followed by the various later manifestations, known as secondary and tertiary lesions, may extend over many years, and may result in greater or less permanent damage to the individual, and in addition may and does in certain cases destroy life.

In addition to the personal distress and danger

to the person affected, we have also to consider the serious risks which are continually run from the infective nature of the disease, both in the more commonly thought of venereal contact, and also in the innocent relations of family, social, and industrial life; as well as in the matter of hereditary transmission, which is almost sure to occur during a certain period or stage of the disease. Unfortunately, the exact duration of this infective period is unknown, for although in many cases it seems to terminate in two or three years, in other instances the disease has been communicated from one to another even after the lapse of many years. Syphilis can be transmitted hereditarily long after its contagiousness appears to have ceased in other directions, and, as far as I know, no limit has been set, after the occurrence of infection, at which offspring may not exhibit, to a greater or less degree, some evidences of the poison having been acquired with their life. All this refers, of course, to untreated syphilis, or that which has been very imperfectly treated.

The other side of the picture is, however, most encouraging. Seen from the beginning and treated properly and faithfully for a sufficient length of time, and under the most favorable conditions, syphilis is easily manageable, need give but little trouble, further infection can be prevented, and, in the opinion of many, the disease is entirely curable. The evidence of its curability, as is well known, has been inferred or deduced from the fact that it can be acquired the second time, whereas the individual who is still syphilitic is not capable of reinfection.

Such, then, being the disease which we have to do with, it remains for us to discuss the subject before us, namely: "the indications for, and the duration of the treatment of syphilis." I do not suppose that it is necessary for us to enter at all upon the symptoms of syphilis or its manifestations, which are familiar to all, except so far as it may be necessary to allude to them in reference to the treatment necessary at the various periods of the disease; and we should rather confine our attention to the form of treatment best at different stages, and the duration of the same, and to the total duration of treatment requisite.

1. The first question for us to consider is, How early should the treatment of syphilis begin; when in the existence of the disease should we commence active treatment calculated to overcome and nullify the poison?

If the disease were produced artificially, as we vaccinate and so communicate the infectious disease vaccinia, or if the entrance of the syphilitic poison were absolutely known, it would seem proper to administer the antidote at once. But, of course, the syphilitic infection is seldom suspected and never known positively until the chancre or primary sore forms at the seat of entry, from ten days to several weeks after the date of

its entry into the system, and the question arises, when should treatment begin?

If there were surely only one class or variety of sores or abrasions known, on the genitals or elsewhere, and that were always the first manifestation of syphilis, there would be little or no question about the matter. But the difficulty of diagnosing these sores is proverbially so great that, unless I am greatly mistaken, every one has at times found it hard to decide just when to give constitutional treatment. Shall we wait, as has been advised, until other manifestations of the disease occur, upon the skin or elsewhere, in order to be absolutely certain of the diagnosis, or shall we begin at once when we have reasonable cause to suspect that the sore is due to syphilis? I leave this and other questions for your deliberation.

2. The second question which must arise to the practitioner's mind is, How long should the treatment be continued? Under active internal medication, and perhaps with the aid of some local measures the sore heals, and all hardness may disappear in a greater or less length of time. Possibly if all circumstances have been favorable, and the treatment has been energetic, there are none of the so-called early secondary manifestations of the disease: no lesions appear on the skin, the throat keeps well, and the hair does not fall. How long should the treatment be continued, and when can we be justified in pronouncing the patient quite fit to cease medical treatment? We are here supposing that the patient fully recognizes his condition and the dangers of the disease, is perfectly faithful to treatment, and is quite willing to abide by the decision of the physician. How soon can his medical adviser permit him to leave off treatment, with the assurance or expectation that he will have no further manifestations of the disease, cannot communicate it to others, and will not transmit it hereditarily?

3. If the patient be unmarried, the question is often asked, how soon he or she can marry after acquiring syphilis? As the answer to this depends largely upon the character and duration of the treatment carried out, it is one which may also well be considered by us in our present discussion.

4. When patients come to us after syphilis has become thoroughly established, and after it has exhibited one or many of its manifestations on the skin or elsewhere, what shall be the duration of our treatment? Shall we give remedies only until the lesions have disappeared or ceased to give annoyance, or shall a regular course of treatment be instituted, and if so, for how long a time?

5. It often happens that some years after the primary infection, possibly after there has been more or less of treatment, late lesions, generally gummy in nature, appear in one or another part

of the body. What shall be our course in regard to them? Shall we simply give remedies until the obnoxious manifestation of the disease has disappeared, or shall we attempt to follow out a definite and continued course of treatment aiming at a more radical and permanent cure of the disease itself?

It would be possible, perhaps, to present many more questions for our consideration, but these, I think, cover much of the ground which often has to be mentally gone over by the physician facing a case of syphilis, and in regard to which he might not find practical aid in reference and text-books. These, therefore, are presented for discussion, in the earnest hope that the result of our deliberations may be both profitable to ourselves in settling our views in regard to the matters alluded to, and beneficial to our patients, in affording them, and consequently others related to them, more satisfactory and permanent relief from one of the worst diseases, when neglected or badly treated, to which the human race is subject, namely, syphilis.

#### THE POSITIVE DIAGNOSIS OF SYPHILIS, WITH SOME INTERESTING MEDICO-LEGAL TESTIMONY,

by EPHRAIM CUTTER, M.D., I.L.D., of New York, was read by his son, Dr. J. A. Cutter.

For twenty years, a method of diagnosis of syphilis has proved so satisfactory that it is deemed positive and also a positive loss to those who do not use it. The mode of physical exploration is simple but delicate. A drop of blood just large enough to fill the space between an ordinary cover glass and an ordinary slide is obtained by puncture on the radial edge of the wrist, which is generally free from hair. Codman & Shurtleff, of Boston, make a scarificator (for the writers) which extracts the blood in a satisfactory way. The drop is transferred to the stage of the microscope, which must be good, to wit, for bacterioscopy. Fortunately good microscopes are more common than they were. If the light is properly adjusted and the observer is sincere and competent, as the syphilitic blood goes through its biological movements in dying, there will be seen here and there more or less numerous, active, automobile, sometimes saltatory, extremely minute globular bodies, called spores or microspores, micrococcus spores or bacteria, of the *Crypta Syphilitica*, which, when dancing or are put out of focus slightly, are copper-colored. The higher the power, the more distinct this color. With the  $\frac{1}{8}$  inch objective of Tolles, the copper color has been found more marked than with any other power. Sometimes these spores will travel across the whole field. They are found in the serum spaces, over the red corpuscles and in the white corpuscles. In old cases, they are found in the urine and specially in the pus of chancres. These spores are the baby stage of the *Crypta Syphilitica*.

(Salisbury). The fully developed form or parent plant is a cylindrical filament, slightly tapering, and is found in the blood in the form of short curved segments, sometimes slightly clavate at one end and in long strings or filaments, in coils, skeins, or comparatively straight. In the walls of chancres they are very curling and spirally twisted like the vegetative filaments of the plant in carbuncle. These crypta syphilitica filaments are also copper-colored when put a little out of focus. The mature plant is not so common as the infantile, which has the power of reproduction in its immature stage and of producing the physical and chemical influences of the mature plant.

The spores are to be distinguished from minute globules of fat whose motion can be seen by putting milk or fat emulsion under the microscope. They sometimes join in pairs like other bacteria, but not often. Their movements sometimes last twenty-four hours after withdrawal, if the cover is protected by the thorough drying of the blood around its edge. Fat globules do not travel across the field save when borne by currents of capillarity, in which everything moves with them. Fat globules will not travel in opposite directions as syphilitic spores do. They are also to be distinguished from the spores of vinegar yeast, *i. e.*, the second stage of development of tubercle bacillus, in the blood, by their want of aggregation and by their mobility.

Vinegar yeast spores occur singly, in pairs, triplets, and so on to massive aggregations which form emboli and, when detained in the lungs, tubercle. In the present stage of knowledge the spores of syphilis are unique in their active, saltatory motions and copper color. These few words are enough to suggest the line of research. The subject is more fit for the pathological or morphological laboratory than a lecture room. Should the sun be available and a proper dark room be found, the writer will project syphilitic blood on a screen and demonstrate the spores thereon with the morphologies of other blood for comparison.

In a late trial for murder, the suspect's clothes were submitted to the writer, apparently stained with blood which had been more or less washed by water. In the study of the morphology of this clothing, a list was made of the objects found under the microscope along with the blood as a matter of detail—not intending to use the foreign bodies as testimony. But the counsel for the defense in his cross-examination told the Judge that he would show that I was not an expert and that I knew nothing about the subject. He then asked, "What did you find in your examination?" Thus challenged the list was partially read, embracing a variety of objects which are not known to many. In the list was included syphilitic spores in active motion and enlarged white blood corpuscles which enclosed syphilitic

spores. These attracted attention in and out of the court-room. Subsequently the physician of the murdered man testified that he was treating him for syphilis at the time of the murder. The jury hung, ten for conviction and two for acquittal. Just before the second trial a physician brought me a slide with blood which he said was taken from a patient whom he thought had syphilis. I found the spores in active motion. At the trial, this same physician was called to the stand, but was non-committal and got away as soon as he could. I was then shown the slide that he had brought to me, and on being questioned testified that I had found the evidence of syphilitic blood in it. It then transpired that a trap had been laid for me, for the blood in the slide was obtained from the prisoner. Still my evidence was positive, for a physician testified that he had treated him for syphilis. This time the suspect was convicted and sentenced for life.

DR. CARL SEILER, of Philadelphia, inquired of Dr. Cutter the shape and size of the spores in question.

DR. CUTTER replied that he could not tell their size; he had not measured them. With 500 diameters the size was very small and varied from one to two, the same as blood corpuscles. Their movement was of greatest importance. Their shape was spherical.

DR. SEILER said he did not wish to intrude himself upon the Section as he was not a member of it, but the subject of Dr. Cutter's paper was one with which he had had a little experience. Ten years ago, at a meeting of the American Laryngological Association, Dr. Cutter had been asked by him the same question which he had just put to his son, and he had got identically the same answer. During that time the measurement and study of spores had vastly improved under

instruments of precision, and it seemed very strange Dr. Cutter had not taken the trouble to measure the bodies spoken of. Besides, it was a well-known property of broken up corpuscles in the blood to take on the movement and brown appearance described in the paper. He had no doubt the so-called spores of syphilis were nothing more than broken up blood corpuscles which danced up and down in the serum and gave a copper color. A strange fact in the presentation of the case was that the higher the power the smaller the cocci appeared. Generally the reverse was true.

DR. FLEISCHNER, of New Haven, feared that even if the observations made by Dr. Cutter were correct, they would prove of little practical diagnostic value to the general practitioner. Yet the thanks of the Section were due the doctor for his researches.

DR. W. B. MATHEWSON, of New Jersey, remarked that if it could be definitely shown that this spore did indicate syphilis the fact would be of great value as placing the diagnosis on positive ground. But thus far, the connection between syphilis and the spore had not been traced. The discovery of the spore of syphilis had been repeatedly asserted. If he remembered correctly, Cornil had found this spore in only about one-third of the cases of actual syphilis. He had seen the spore himself frequently in blood examined, both in syphilitic and healthy persons. The trial to which the author had alluded showed, he thought, a recklessness in testimony of which the medical profession should never be guilty.

DR. ROOT, of Hartford, thought the paper well worth consideration. He remembered that once the blood of some patients in a hospital in New York City had been sent to Dr. Cutter for examination, also some from the house physicians, and while the house physicians did not admit the truth to Dr. Cutter, yet to outside parties it was admitted that his diagnosis was correct in every instance.

DR. E. N. BRUSH, of Philadelphia, said that about 1878 he heard Dr. Ephraim Cutter make similar statements when in Buffalo, and he attempted to confirm them by observations of his own. Perhaps his objectives were not of sufficient power; at any rate, he was unable to make out anything of diagnostic value. He found the so-called spores of syphilis in persons who surely did not have syphilis, and he failed to find them in persons known to be syphilitic. He did not wish, however, to throw any discredit on Dr. Cutter's work. Certainly if there were a bacillus or spore of syphilis it would be very desirable to find it, but it should be remembered that it had been looked for many years, that spores of various shapes and colors had presumably been discovered, yet his own work, and the better work of some of his friends in the profession, had failed to confirm the discovery.

DR. CUTTER said, in closing the discussion,

that his father had simply desired to bring before the profession an easy and certain way of diagnosing syphilis. If the sun were not obscured later he would demonstrate the spores with the solar microscope.

DR. CARL SEILER, in discussing some of the points raised in Dr. Bulkley's paper, said that his experience with syphilis had been mostly limited to the treatment of its manifestations in the throat, consequently he knew very little about the chancre. He wished the opinion of the members whether it was good treatment to remove by surgery gummata when found in the mouth and nose. He had himself found that when the gummata were situated on the nasal septum, predisposing to stenosis, better results were obtained after scraping them with the curette and then going on with the usual treatment. In that way he obviated many of the difficulties consequent upon nasal stenosis, and obtained quicker results than without. Referring to a point raised by the chairman, he said that in his opinion, when local lesions of this kind existed they demanded both local measures and internal remedies. Quick measures should be used, such as the hypodermic injection of solution of bichloride of mercury. This he constantly employed until the lesions disappeared, and then placed the patient on mixed treatment for a considerable length of time afterward. He thought it bad practice to stop treatment as soon as the lesions disappeared. When asked what he considered sufficient time, Dr. Seiler replied about two years.

DR. CORLETT had been in the habit of giving the patient a placebo until it could be decided whether his chancre were a hard or soft one, not wishing to modify the disease by any remedy until a positive diagnosis could be made. During the past year, however, after reading Jonathan Hutchinson's report, he had somewhat changed his way of handling his patients, putting them upon mercurial treatment as soon as he thought syphilis was present. It was his opinion that the better rule was to wait until induration took place in the chancre and the lymphatic glands became involved before resorting to mercurial treatment. He would then place the patient on mercurial treatment and continue it for at least a year after all symptoms had disappeared. As to removal of the chancre, he thought it good practice when situated where its removal would not involve important parts. In the few cases in which he had seen it removed the disease ran a mild course afterward, which may have been due to the removal of the chancre. If a case presented itself before induration of the lymphatic glands he would most assuredly remove the chancre, if possible by the knife, if not, then by a strong cautery. On the glans penis the cautery would be preferable.

As to the medicine to be used during the second

stage, he believed the only drug which had the power of eliminating the syphilitic poison was mercury. It not only had the power of removing existing lesions, but of shortening the disease. Potassium salts would cause the lesions to disappear, but not were more prone to return. He quite agreed with Dr. Seiler, that it was necessary to continue the treatment two or three years, and at least one year after the symptoms had disappeared.
